

The background of the cover is a vibrant landscape photograph. In the foreground, there are dark green evergreen trees. Behind them is a calm, blue lake. The far shore is lined with a dense forest of green trees. In the background, majestic mountains with patches of snow rise against a clear blue sky. The title is overlaid on a dark grey rectangular box in the upper half of the image.

ENCYCLOPEDIA OF LAKES AND RESERVOIRS

Volume Editors

Lars Bengtsson is professor in Water Resources Engineering at Lund University, Sweden. He was previously professor of hydrology at Uppsala University and Luleå Technical University and visiting professor in the USA, Canada and Hungary. He is and has been editorial board member of a large number of scientific journals. He has published more than 100 papers in international peer-reviewed journals. He specializes in physical processes in lakes and rivers and cold climate hydrology.

Reginald Walter Herschy is a British consultant in hydrology dealing mainly with rivers, lakes and reservoirs. His work has taken him to Ireland, China, India, South Africa, Lesotho, Kenya, USA, Canada and South America. He was formerly with the UK Government for many years as head of hydrometry in England and Wales. He is the author of some 60 technical papers on hydrology and meteorological satellites and several books. He is co-editor with the late Professor Rhodes Fairbridge of the Encyclopedia of Hydrology and Water Resources.

Aims of the Series

The *Encyclopedia of Earth Sciences Series* provides comprehensive and authoritative coverage of all the main areas in the Earth Sciences. Each volume comprises a focused and carefully chosen collection of contributions from leading names in the subject, with copious illustrations and reference lists.

These books represent one of the world's leading resources for the Earth Sciences community. Previous volumes are being updated and new works published so that the volumes will continue to be essential reading for all professional earth scientists, geologists, geophysicists, climatologists, and oceanographers as well as for teachers and students. See the back of this volume for a current list of titles in the *Encyclopedia of Earth Sciences Series*. Go to <http://www.springerlink.com/reference-works/> to visit the "Earth Sciences Series" online.

About the Series Editor

Professor Charles W. Finkl has edited and/or contributed to more than eight volumes in the Encyclopedia of Earth Sciences Series. For the past 25 years he has been the Executive Director of the Coastal Education & Research Foundation and Editor-in-Chief of the international *Journal of Coastal Research*. In addition to these duties, he is Professor at Florida Atlantic University in Boca Raton, Florida, USA. He is a graduate of the University of Western Australia (Perth) and previously worked for a wholly owned Australian subsidiary of the International Nickel Company of Canada (INCO). During his career, he acquired field experience in Australia; the Caribbean; South America; SW Pacific islands; southern Africa; Western Europe; and the Pacific Northwest, Midwest, and Southeast USA.

Founding Series Editor

Professor Rhodes W. Fairbridge (deceased) has edited more than 24 Encyclopedias in the Earth Sciences Series. During his career he has worked as a petroleum geologist in the Middle East, been a WW II intelligence officer in the SW Pacific and led expeditions to the Sahara, Arctic Canada, Arctic Scandinavia, Brazil and New Guinea. He was Emeritus Professor of Geology at Columbia University and was affiliated with the Goddard Institute for Space Studies.

Preface

Lakes are formed when depressions are filled with water. Reservoirs are artificial lakes created behind a dam or between dykes. There are nearly nine million lakes in the world with a total surface area of about 1,600,000 km² and a total volume of 230,000 km³. In this encyclopedia, a lake is referred to as a water body with an area of at least 2 ha. Smaller water bodies are referred to as ponds and outnumber the lakes. Lakes and reservoirs are used for many purposes such as for water supply, fishing, recreation, irrigation, aquaculture, transportation, and receiving waters. Most of the large lakes and reservoirs in the world are described in detail in this encyclopedia. Smaller lakes are presented based on regions or countries. Also included are wetlands such as bogs, fens, and coastal marshes. Since the processes in semi-closed coastal basins are similar to those in lakes, estuaries and coastal lagoons are also discussed in this encyclopedia.

Most lakes are freshwater lakes, but by far the biggest one, the Caspian Sea (370,000 km²), is a salt lake with its surface below the sea level. Many lakes are situated in the northern part of the Northern Hemisphere, and were created when water filled depressions formed as the land ice retreated. These lakes are usually rather shallow and often situated clustered together. Lakes formed by tectonic uplift can be millions of years old. Lake Baikal is believed to be 20 million years old. However, a lake does not exist forever. Sediments from rivers can fill the lake, which becomes shallower and in due course becomes a wetland and finally a forest. This process takes thousands of years. Under the influence of humans, the process may be accelerated when lakes are loaded with nutrients.

Reservoirs have been built for some 5,000 years in different parts of the world, the oldest dam being Sadd el-Kafara built about 2,800 BC in Egypt. One of the oldest reservoirs still in existence today is Mannoh-Ike in Japan built in the ninth century AD.

Different physical, chemical, and biological processes take place in lakes, the most important, perhaps, being

the water balance, which refers to the balance between inflows and outflows and water storage. The water quality in a lake is determined, to a great extent, by the conditions in the upstream river basin. Within the lake, the water circulates and mixes with the help of the wind and solar radiation. A lake may receive several pollutants from human activities. The thermal conditions within a lake largely determine how different waters are mixed, and together with the light conditions and the nutrient status influence the primary production and biological life. All these processes are very different in shallow lakes and in deep lakes and also vary between small and large lakes.

Most lakes have an outflow that helps regulate the lake's water level. However, there are some low-lying lakes with no outflow. These terminal, or endorheic, lakes are very sensitive to climate variation and to human activities within the upstream river basin. A small change in the river inflow results in changed water level and consequent change in the lake area. This is seen clearly in the Dead Sea and the Aral Sea, where the lake areas have been reduced considerably. Terminal lakes are usually salt water lakes, the Dead Sea being an extraordinary example.

The objective of the *Encyclopedia of Lakes and Reservoirs* is to present the current state of scientific understanding of various aspects of the earth's lakes. A comprehensive overview of diverse though interrelated topics is provided. There are about 200 entries. The encyclopedia takes on a rather physical-geographical approach in that the lakes are characterized from surface area, depth and their hydrological characteristics, water balance, thermal regime, and river basin conditions. For individual lakes, different aspects of water quality are also included; for many lakes, circulation processes are described as well. The basics of physical, chemical, and biological processes are covered in a large number of separate specialized entries. Most entries are presented in a way the reader can benefit from even if they are outside of his or her expertise. Some other entries are informative

while others are specialized at a high theoretical level. There are also many entries that deal with engineering issues, focusing on how to solve different problems. Effort has been made to provide comprehensive coverage of different aspects of lakes and reservoirs. However, processes that require advanced mathematics to quantify are not dealt with in great detail.

The physical processes that have been treated are circulation and mixing of different waters, light-penetration and formation of thermal stratification, ice growth, and sedimentation. Sedimentation and resuspension of bottom material influence the water quality in a lake to a great degree, since different substances are brought into a lake with materials in suspension. Sediments brought into reservoirs shorten the lifetime of reservoirs. Chemical and biological processes that have been covered include nutrients in different forms, carbon cycle, eutrophication, bacteria, and various types of aquatic vegetation. Water quality, health aspects, and environmental issues are treated in special entries but are also directly related to many of the lakes. The water quality in lakes is important as it determines how the water can be used and regulates the biological life of the lake. The influence of physical processes on the nutrient cycle and biological life becomes clear from the entries that describe the changing conditions in lakes in detail. Circulation, nutrient balance, light penetration, and carbon cycle are all key to determining the status of a lake. Multipurpose use, conflicts, and social and ecological impact of reservoirs are discussed in some entries. A number of entries cover paleolimnological studies of lakes, while some others deal with expected future conditions in light of climate change, which, along with global warming, is at the center of public debates, professional forums, news media, and political dialogue. Finally,

the dynamic development of the world's lakes is discussed in detail in this encyclopedia.

The *Encyclopedia of Lakes and Reservoirs* is structured for quick access to particular terms and concepts in self-contained entries. The many overview entries should arouse the reader's curiosity about the different facts, problems, and processes related to lakes and the influence of humans on lakes and reservoirs. It is hoped that the encyclopedia will serve as a reference to scholars and students; it will be a resource for hydrologists, geographers, geologists, climatologists, limnologists, ecologists, biologists, physical planners, and water resource engineers, as well as to those who are engaged in the agricultural and civil engineering, earth sciences, and other relevant fields. The entries in this encyclopedia are divided into three categories: A, B, and C. Entries in category A represent major divisions and review topics. These also serve to coordinate the scattered entries in categories B and C. Entries in category B constitute items that are typically textbook sub-heads. Entries in category C consist of mini entries that deal with definitions, concepts, and short explanations of various phenomena. Entries are presented in alphabetical order. If the reader cannot find a suitable entry, it is suggested they refer to the index, since the topic may be covered under a different heading or be part of a larger entry.

The creation of this encyclopedia, like others in the series, has been possible only because of the cooperation of our wholehearted contributors representing more than 30 countries.

Lars Bengtsson and Reginald W. Herschy
Editors-in-Chief

A

ACIDIFICATION IN LAKES

Thomas Hellström
Thellva HB, Dalarö, Sweden

Definition

A lake can be considered acid or slightly acid when pH is below neutral (<6.5). More evident biological consequences will develop at $\text{pH} < 5.5$.

Acid lakes have either natural or anthropogenic reasons.

Natural acid lakes are situated near peat bogs in northern regions (mainly in Russia, Canada, USA, and Scandinavia). Peat bogs emit organic acids (fulvo and x acids), which cause lakes to become acid. Many of such acid lakes are without fish.

Acid lakes due to anthropogenic impact get a considerable input of acid rain (including dry deposition). Through burning of fossil fuels (especially coal) without proper emission control of acid substances large amounts of acid substances have been emitted. The major acid substance is SO_2 (H_2SO_4). Nitrous oxides (HNO_3) and chlorides (HCl) also have an impact. These substances emitted as gases can be transported long distances until they reach ground either in a wet or dry form. Also ammonium (NH_4^+) will have an acidifying effect although it is in most cases originally emitted as ammonia, which have no acidifying effect.

Soil through weathering has a neutralizing effect. If the soil is calcareous no acidification can occur due to acid atmospheric deposition. With a coarse soil of noncalcareous matter the situation is different. Especially when the soil cover is very thin above ground rocks or nearly nonexistent the neutralizing effect is strongly limited.

Together with direct acid atmospheric deposition to a lake and acid runoff to a lake, pH in a lake can be low.

Acidified soil will leach out aluminum and other substances (iron), which will precipitate in the lake. In the

precipitation phosphorus is adsorbed and will be put into the sediments. Potentially acid sensitive lakes have naturally rather low phosphorus levels. Increased leaching of mainly aluminum due to acidification will through precipitation put the phosphorus levels to even lower levels. The production in acid lakes is therefore very low.

Acid lakes except impact on algal growth have a negative impact on fauna. Animals dependent on a calcareous skeleton get problems. That has a negative impact on crayfish and fish at low pH levels.

AFRICA, LAKES REVIEW

Rhodes W. Fairbridge (Deceased), Lars Bengtsson¹

¹Department of Water Resources Engineering, Lund University, Lund, Sweden

Introduction

The African continent with its offshore islands covers 30.1 million square kilometers, the islands including the Canary Islands, Cape Verde group, Reunion, Mauritius, etc. There is also Madagascar, with 590,000 km², often classed as a “subcontinent.” Africa is bordered by the Atlantic on the West, the Indian Ocean on the East, and the Mediterranean on the North. The continent is bisected by the equator, extending from Gabon to southernmost Somalia. N–S it extends 8,000 km, from 37° North almost to 35° South. The mainland stretches 7,500 km, from 17° West to 51° East. In area, there is about twice as much in the northern hemisphere as in the southern.

Geologically, Africa is an integral part, the central part of the ancient Gondwanaland which started to break up about 250 Myr ago. The old continent had been brought together as a complex of still older Precambrian crustal blocks, united during the Pan-African orogeny about 550 Myr ago. Subsequent to that unification, each of the “tessera” blocks underwent a long history of alternating downwarping and uparching that created a megamorphology which defines the present-day drainage basins like the Congo (Zaire), the upper Niger, and the White Nile. Both East and West margins are truncated cratonic borderlands. However, the NW and South margins are marked by E-W orogenic belts, the southern one (the “Capeides”) dating from late Paleozoic folding, and the northern one (the Atlas/Maghreb ranges) from late Mesozoic and Cenozoic folding. Probably the most striking feature of African geotectonics at the present time is the East African–Red Sea rift zone, a global scale taphrogenic feature that is generally regarded as still-another fracture zone of the post-Gondwana breakup which may well anticipate a new oceanic seaway. These fractures tend to a zigzag pattern, resulting in star-like “triple-point” intersections. Where the South American continent broke away in the Gulf of Guinea, the third branch, a so-called failed arm (known as an “aulacogene”) is represented by the Niger delta and the lake-occupied Cameroon belt.

Volcanoes mark the mid-cratonic triple points in centers like the Hoggar in southern Algeria or the Tibesti at the Libya-Chad border. The East African rift zone from the Red Sea to Mozambique is dotted with volcanoes, many with highly alkaline lavas, which control the chemistry of nearby lakes. One totally unique crater is Lake Bosumtwi in Ghana, the impact site of a major asteroid.

Climatologically, Africa is dominated by its position astride the equator which coincides with the drainage basin of the Congo and is largely occupied by rainforest in the lower elevations though replaced in the higher eastern plateaus by forested savannas. Borders of the great rift valley lakes are marked by vertical environmental sequences, and some of the major volcanic slopes display a dramatic sequence passing upward through equable mid-latitude forest zones into tundra and eventually permanent snow fields (e.g., Mt. Ruwenzori, Mt. Kenya).

North and south, around 10–20° North and South, are the typical savanna lands that are visited regularly by the monsoonal rains as the heat equator shifts North or South. These rains often come in two wet seasons, once as the monsoonal front passes over and once as it returns. This savanna belt is very much more extensive in the northern hemisphere where it is known as the “Sahel,” extending from Senegal to Eritrea.

Likewise paired are the two high-pressure arid belts, the Sahara Desert in the north, the Kalahari in the south, though again the Sahara-Libyan-Arabian belt is far wider. Here we need to recall the long-term effect of the planetary orbital precession (of about 18,000/23,000 year) which switches the Earth’s closest approach to the Sun: now in

the southern hemisphere, but in the northern about 10,000 years ago. This had the effect then of bringing the monsoonal rains across the Sahara to the borders of the Mediterranean and many paleolakes are found here today. In most cases, these former lakes are traceable only by their diagnostic deposits and large accumulations of shells and the bones of now extinct creatures, fish, *hippopotamus*, crocodiles, and bird life. In a few cases, there are still natural springs that keep the lakes in existence as oases. According to the Egyptian astronomer Ptolemy, in the first century AD, there were occasional summer thunderstorms at the latitude of Alexandria that are not known today.

Mediterranean-style climates are found in the northern and southern fringes of Africa. In the north, the rains come in the early months of the year (January–March); in the south, the opposite (August–October). They respond to the cyclical nature of the prevailing westerlies. These are interrupted by occasional outbursts of polar anticyclones that may bring associated precipitation as far south as Morocco and Mauritania when the Western Sahara may become dotted with small ephemeral lakes. At the higher elevations of the Atlas Mts, snowfall is a regular feature of winter seasons. On rare occasions, these winter snows reach as far south as the mountains of Ethiopia, and even the Nile at the latitude of Cairo has been known to freeze.

The coastal currents also affect the precipitation patterns. On the West, the S-setting Canaries Current is extremely cold, so that powerful temperature inversions bring arid conditions to the coast, and likewise in the South where the cold N-setting Benguela Current brings hyper-aridity to the Namib Desert of Namibia. In contrast, on the East coasts of Africa, the warm Mozambique Current brings heavy precipitation.

Political ups and downs make some of the citations rather confusing. Togoland, a former German colony, became divided, the West part being now attached to Ghana (1957) and the East part is now an independent state, Togo (since 1960). The French colony Dahomey (of 1844) has become Benin. The Belgian colony of Congo Belge became Zaire (in 1960), but has since reverted to “Congo.” The two lakes, “Lake Mobutu Sese Seko” and “Lake Idi Amin,” have both passed the way of all flesh. Lake Rudolf has become Turkana. Lake Nyasa (or Nyassa) and Lake Malawi are still undecided (Figure 1).

Classification of African lakes

Epeirogenic basins (broad downwarps of the Craton)

1. *Lake Chad*, Rep. Chad, Niger, and Nigeria (lake: 22,200 km²; drainage basin: 1,200,000 km²). Present inflow: 45.8 km³, fed by seasonal rains from Central African Republic, Niger, Nigeria, and Cameroon. No outlet (endorheic). It once reached from the Aïr to the Ouddaï, with an upper level 284 m above sea level, and an area approaching 300,000 km². Evaporation calculated at 2.26 m. During wet cycles of the geological past, a “Paleochad” existed that reached to the

Africa, Lakes Review, Figure 1 Distribution of lakes in Africa (After Herdendorf), 1, Chad; 2, Ngawi; 3, Bansweu; 4, Mweru; 5, No; 6, Debo; 7, Albert; 8, Hoggar; 9, Tassili n'Ajjer; 10, Tanganyika; 11, Victoria; 12, Nyasa; 13, Kariba; 14, Chilwa; 15, Rudolf; 16, Volta; 17, Aswan; 18, Aby; 19, Kyoga; 20, Tana; 21, Kivu; 22, Nhlange; 23, Edward; 24, Asale; 25, Magadi; 26, Faguibine; 27, Chamo; 28, Tumba; 29, Udemba; 30, Nai' Ndombe; 31, Rukwa; 32, Tibesti; 33, Ennedi.

margins of the present drainage basin. In 1995, an important discovery was made in Pliocene deposits that included an australopithecine, along with a rich fauna of mammals, fish, etc. which suggest a savanna with ephemeral rains.

2. *Lake Ngawi and Okavango Swamp*, Botswana.

Fed by multiple rivers from central Angola, lake expands enormously during southern rains, creating an interior delta, the Okavango Swamp. It has no outlet besides evaporation. Its biotopes are comparable with those of Lake Chad.

3. *Lake Joliba and others*, Mali. Seasonal lake related to the Niger's inland delta, which assumes major lake characteristics following the monsoonal rains.

4. *Lake Mweru*, in the Katanga which is the southern region of the Congo basin.

This lake has intake from the Chambezi in Zambia (explored by Livingstone in 1871), and its exit with many waterfalls emerges as the Luvua, and further downstream with the Lualaba. The latter is considered to be the principal source of the Congo. It receives some overflow from Lake Tanganyika.

5. *Lake No, and Nile Inland Delta, in the Sudd*, southern Sudan.

The Sudd is a swampy section of the White Nile (Bahr el Abiad in Arabic), which expands into an inland delta that has lake to swamp characteristics depending on the season. The northern end is marked by Lake No, a perennial feature.

6. *Lake Debo and Niger Inland Delta*, Mali. Comparable with that of the Nile, the Niger forms a giant ephemeral lake covering up to 20,000 km² in the wet season (October–December), its surface falling from 272 to 262 m above sea level. Lake Debo is in the lower section of the delta and is only 6 m deep at its maximum. Bounded on the NW side by the Saharan desert sands, at the high-water stage, the interdune depressions fill to create secondary lakes.

Epeirogenic upwarp centers

These include the Hoggar (Ahaggar) and Tassili n'Ajjer in southern Algeria, the Tibesti and Ennedi in northern Chad. Because of their elevations, they attract precipitation in the otherwise hyperarid regions of the Sahara. Radial wadis fill during rainstorms and feed into ephemeral lakes. Some rare, deeply scoured depressions maintain perennial water bodies, e.g., Djanet Oasis. They dry out into hard mudflats known as *sebkhas* (in the French-speaking regions; "*sabkhas*" in others). Examples in the area north of the Hoggar include the Tidikelt Plain with: *Sebkha Azzel Matti*, *Sebkha Meckerrhane*, *Azir*, *Chebbi*, etc.

Orogenic fold-belt lakes

In the depression between the Northern Atlas and the Southern Atlas of Algeria, there are extensive swampy or ephemeral lake bodies, e.g., *Chott ech Chergui*, *Chott el Hodna*, etc.

Also along the southern margin of the Atlas, there are numerous wadis that flow seasonally for 100 km or more and dissipate into the sands of the Sahara, or in some cases where there is structural subsidence, there are quasi-permanent chotts (also spelled "*schotts*"), *Chott Melrhir* and the *Chott el Djerid* (in Tunisia). The last named has connections to the Gulf of Gabes in the Mediterranean, and during positive eustatic oscillations, it has been inundated by the sea.

In the Western Sahara and southern Morocco, there are lower elevations which also catch some seasonal rains, feeding wadis that dissipate in large *sabkhas*, e.g., *Sebkhat Oum el Drous Guelebit*.

Structural troughs (taphrogenic, graben forms)

1. *Lake Tanganyika*, largest in capacity of the east African "great lakes," bounded by Tanzania, Congo (Zaire), Zambia, and Burundi, its area is 32,900 km² (12,700 mi²), while its capacity is 18,900 km³ (4,534 mi³) which reflects its tremendous depths (1,582 m, 4,823 ft). It is 773 m, (2,535 ft.) above sea level. Its length is 676 km (420 m). Its drainage basin is 237,000 km², fed by rivers along the rift valley,

notably the Malagarasi R. that debouches South of Kigoma. At the North end is the Ruzizi (Russisi) R. that carries the overflow from Lake Kivu. On the NE shore is the Kalambo R. which has a spectacular falls of 215 m (704 ft.), one of the highest in the world. There is a small overflow on the West side at Kalemle into the Lukuga to join the Congo above Kongolo.

2. *Lake Victoria*, largest lake (in area) in Africa; it is bordered by Kenya, Tanzania, and Uganda. It occupies a basin midway between the western and eastern branches of the Rift system. It has an area of 68,800 km² (26,563 mi²) with a volume of 2,700 km³ (649 mi³), being generally rather shallow. There are many islands, large and small. Its drainage basin is 190,000 km² which includes the ultimate source of the Nile, the Kagara R. The Nile's exit was formerly the Ripon Falls, to the Victoria Nile, but somewhat downstream (3 km) the Owen Falls hydroelectric dam at Jinja, built in 1954, controls the outflow (and submerged the Ripon Falls). Lake Victoria is at present 1,134 m (3,720 ft.) above sea level, but it fluctuated somewhat in time with the 11-year sunspot cycle, and in mid-Holocene time was more than 3 m higher.
3. *Lake Nyasa (Malawi)* is Africa's third largest lake, bordered by Malawi (former Nyasaland), Mozambique, and Tanzania, which is 30,044 km², marking the convergence of the eastern and western rifts, and 575 km (360 mi) long, while only 25–80 km (15–50 mi) across.

It is 474 m (1,555 ft.) above sea level, and its maximum depth is 695 m (2,280 ft.), thus 221 m below sea level. Its drainage basin is 94,100 km² (36,332 mi²). Its major intake is the Ruhuhu R. in the north, from Tanzania, which has considerable fluctuations, approximating the 11-year sunspot cycle, and causing oscillations of the lake level of up to 7 m. Its exit is via the Shire R. which is a tributary of the Zambezi. The name "Nyasa" simply means "lake" in the local language, but neighboring states seem to prefer Nyasa.

Lake Nyasa has existed in various forms since Cretaceous times and its early lacustrine sediments contain dinosaur fossils. Tertiary and Quaternary lake terraces occur at up to 300 m above the present lake surface. Lake Chilwa (Shirwa), about 130 km long, is located a short distance SE of Lake Nyasa.

4. *Lake Turkana (Rudolf)*, 6,405 km² (2,473 mi²), lies in the semiarid region of NW

Kenya, with a small overlap into SW. Ethiopia, being seasonally fed by the waters of the Omo River which rises in central Ethiopia, a drainage basin of 153,000 km² (59,060 mi²). Climate changes there have fluctuated greatly and former lake shores are found at over 100 m above the present level (375 m or 1,050 ft. above sea level). The depth is now 73 m. Its southern part is blocked by volcanic materials, and an ash cone was active as recently as the late nineteenth century. The area is of major interest for

paleoanthropology because of abundant traces of early Man and hominids, who clearly flourished in the formerly well-watered environments.

5. *Lake Albert*, 5,300 km² (2,075 mi²), is situated in the Western Rift and bordered by Congo (Zaire) and Uganda. It is sometimes called “Albert Nyanza” (as proposed by its discoverer, Sir Samuel Baker in 1864). The outlet to the North is through the Murchison Falls, after which, it is joined by waters from the Victoria Nile from the NE, and is then called the Albert or “Albertine” Nile, also known as the Bahr el Jebel (in Arabic). Its drainage basin is 18,000 km² (6,950 mi²) with an input of 24.9 km³ (6 mi³). Situated 619 m (2,030 ft.) above sea level, the depth is 50 m (168 ft.). The lake is 618 m (2,039 ft.) above sea level. To the South lie the Ruwenzori Mts (Ngaliema: 5,080 m, 16,763 ft.), that are said, according to Ptolemy, the Egyptian astronomer, to be the classical “Mountains of the Moon.” In the SW, it receives intake from waters of the Semliki R. which carries the overflow from Lake Edward.
6. *Lake Kyoga*, 4,429 km² (1,710 mi²), situated in the basin north of Lake Victoria, in Uganda. It is 80 km (50 mi.) long but only 8 m (25 ft.) deep. The Victoria Nile flows into it from the East and exits from the north. Its drainage area is about 75,000 km² (29,000 mi²). Its surface inflow is 24.1 km³ (about 5 mi³).
7. *Lake Kivu*, 2,700 km² (1,042 mi²), is located in the West rift between Lake Tanganyika and Lake Edward, with a drainage basin of 4,360 km² (1,680 mi²). It drains to the north to Lake Edward and south to Lake Tanganyika (Ruzizi [Russisi] R.). It is bordered by Rwanda and Congo. Measuring about 95 × 48 km (59 × 30 mi) at an elevation of 1,460 m (4,790 ft.), with a depth of 445 m (1,460 ft.), it is said to be the most beautiful of the Rift Valley lakes, at the center of a cluster of major volcanic cones, all above 3,300 m. Serious overpopulation leads to disastrous soil erosion.
8. *Lake Edward*, 2,510 km² (830 mi²), is situated between Uganda and Congo (Zaire), to the South of Lake Albert, with which its outlet is linked by the Semliki R. It is about 135 × 80 km (50 × 30 mi). Discovered by Stanley in 1889, it was once called “Albert Edward Nyanza,” and far to the NE, there is a connection with the smaller Lake George through the Kazinga Channel. The principal intake is from the Rutchuru R, sometimes taken as a western tributary of the Nile. Its drainage basin is approximately 20,000 km² (7,700 mi²) and is 912 m (2,991 ft.) above sea level. Several volcanic crater lakes exist in the vicinity, with no outlets and thus saline, one being the source of a salt industry.
9. *Lakes Asale (Assal) and Afdera* are hyperarid bodies located in the Eritrea/Ethiopian border area, in the Danakil Rift or Afar Depression, which is the extension of the East African Rifts in the Afars Triangle, thus leading into the Red Sea structures. Asale is the saltiest major lake (348 g/l), covering 57 km², at

155 m below sea level with a maximum depth of 40 m. The hydrology is seasonally fed by occasional rains in the eastern plateau (via the Kalou R.), but largely desiccated in the dry season. There are small, freshwater springs. The area is surrounded by glistening white salt flats notable for their spear-head crystals of gypsum, and encrustations of pink halite. Seasonally banded with fluvial sediments, the whole evaporite sequence is 20–80 m thick. The sale is exploited by Arabs who transport it as far as Tibesti.

10. *Lakes magadi (620 km²) and natron*, two shallow saline lakes resp. In South Kenya and North Tanzania, associated with large soda (trona) deposits. At several stages of the Pleistocene and Pliocene, there were large freshwater lakes here, apparently filled by much more abundant rains.

Volcanic lakes

Africa has at the present time no active subduction zone and thus no volcanic arcs. It has, however, mid-plate fractures and the rift zone where volcanoes are quite prevalent.

1. *Rift zone volcanoes* provide small crater lakes in several areas such as North of Lake Kivu in the West Rift, also near Lake Edward.
2. *Lake Tana* (Tana Hayk), 2,625 km² (1,400 mi²), the largest lake in Ethiopia, was created by lava flows which blocked the drainage system of the Little Abai R. It is 557 m (1,829 ft.) above sea level. The overflow into the Abbai proper becomes the headwaters of the Blue Nile (Bahr el Azraq in Arabic) which joins the White Nile (Bahr el Abiad) at Khartoum. Lake Tana is fed by seasonal floods during the monsoon.

Artesian-spring lakes

These are widespread in the Sahara, providing the basis for many oasis water supplies, and associated lakes. In the recent geological past (c. 2,000–10,000 year ago), a strengthened monsoon brought summer rains across the Sahara and paleolakes became abundant. They are dramatically identified today by former beach deposits and enormous piles of shells, fish bones and remains of major organisms including crocodiles and hippopotamus. Shrunken in size, a number of oasis lakes survive, e.g., in the Egyptian Western Desert: Siwa Oasis, several in the Qattara Depression, Bahariya Oasis, Farafra Oasis, Dakhla Oasis, and Kharga (the “Great Oasis”). At “*Lake Sitra*,” a paleolake in the Sitra Oasis of the Egyptian “Great Sand Sea,” there are freshwater deposits aged 38–19kyr ago. They correlate with similar paleolakes in NW Sudan and the Rub-al-Khali of Arabia. They occur at 9, 16, and 34 m above the present lake level. In the western Sudan there is the Selima Oasis, and the Merga Oasis in northern Darfur. Best known in eastern Libya is the Al Khufrah Oasis. In western Libya, there is the very remarkable “paleolake” of Ash Shati of interglacial age, found in the Fezzan area of SW Libya. Peripheral to the hilly areas here, there is a radial network of wadis that

run in wet seasons and then fill (temporarily) the normally dry ephemeral lakes. A good environmental indicator of the paleolakes is the bivalve *Cardium glauca*, a normally marine form adapted to seasonal salinity changes.

Coastal lagoons

These are extremely numerous, too common to enumerate, but a universal feature of the western coasts of the continent and the eastern, south of the Red Sea, where coral reefs tend to inhibit the wave action on littoral sands, needed to construct the littoral barriers. They are also infrequent along the more rocky Mediterranean shores.

Of interest is Lake Nhlangwe in Zululand, the largest lake in the Kosi system, where there is a 6–8 m terrace, 5 km W of the present coast. Its age is probably Eemian, and its environment a mix of marine and freshwater indications.

Dams and reservoirs

The oldest dams built for irrigation and flood control were those on the Nile, in upper Egypt (the Aswan Dam), and in the Sudan (Sennar Dam). These have been subsequently rebuilt or enlarged, the major one being the so-called High Dam (El Ali) at Aswan creating the *Lake Nasser* which reaches upstream into the Sudan as far as the Second Cataract.

Another major man-made lake is *Lake Volta* created in the state of Ghana, extending over half the length of the country. A third was created by the Kariba Dam and *Lake Kariba* on the Zambezi R. in Zimbabwe and Zambia. A fourth was built on the Atbara R., a major tributary of the Nile, situated in the Sudan near the Ethiopian border at *Khashm el Girba*, the lake being over 50 km in length.

The creation of inland seas, extensive canals and other water bodies subject to evaporation, has been proposed from time to time (e.g., see Lamb, 1977), but has been emphatically rejected by most hydrologists and geologists.

AGE DETERMINATION OF LAKE DEPOSITS

Barbara Wohlfarth

Department of Geological Sciences, Stockholm University, Stockholm, Sweden

Synonyms

Chronology of lake sediments; Dating of lake sediments

Definition

Dating the depositional age of lake sediments and sedimentary rocks.

Dating methods

Lake sediments can be dated using absolute, relative, and/or radiometric dating methods. The different methods have different age ranges. Absolute dating methods are those that make use of counting of distinct annual and seasonal layers; these layers are preserved in lakes with anoxic bottom water conditions and absence of burrowing organisms and can be counted by the naked eye or under the microscope. Relative or age-equivalent dating methods compare specific events detected in the sediments (e.g., volcanic ash, biotic, geophysical, and geochemical changes) with the same events dated in another lake or elsewhere to create an age model. Comparisons and calibrations against the astronomical time scale are used for sediments or sedimentary rocks that are older than 150,000 years. Radiometric dating methods make use of the radioactive decay of isotopes (e.g., ^{14}C , ^{210}Pb). For dating young, up to 130-year-old lake sediments, natural (^{210}Pb) and artificial (^{137}Cs , ^{241}Am) fallout radionuclides are used. The most conventional method for dating the organic fraction in lake sediments 50,000 years back in time is radiocarbon (^{14}C), which relies on a progressive isotopic decay with time. The intensive use of ^{14}C dating since its introduction in the 1950s has led to a comprehensive understanding of the limits and potentials of this method, such as temporal or spatial variations in past ^{14}C levels and contamination of samples. To correct for temporal variations, ^{14}C dates are calibrated against internationally established calibration curves; to avoid spatial variations and contamination, only carefully selected terrestrial plant material is used for dating. Accelerator mass spectrometers now allow ^{14}C dating of material with a weight of < 1 mg. Other methods include, for example, U/Th dating of carbonate-rich lake sediments, infrared stimulated luminescence (IRSL) dating for mineral-rich lake sediments, or $^{40}\text{K}/^{40}\text{Ar}$ and $^{40}\text{Ar}/^{39}\text{Ar}$ dating of volcanic ash layers embedded in lake deposits.

ALPINE LAKES

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Definition

Thomas (1969) divides the central European Alpine lakes into the following groups:

1. Bavarian lakes situated on the Swabian-Bavarian plateau at about 500 m.a.s.l in calcareous-rich catchments; lakes in the Salzkammergut

2. Carinthian lakes, situated in mountains in the south of Austria; sample (1976) has listed 1,270 lakes above surface areas of 0.01 km²
3. Southern Alps (Italy and Switzerland mainly receiving water from crystalline regions of the Alps)
4. Lakes of the higher Alps usually of low salt content with a few being meromictic.

Dokulil (2005) has listed a selection of 60 Alpine lakes from the above groups in Table 1 and Figure 1.

Synonyms

Alternate states; Alternative domains; Alternative structural regimes

Definition

Alternative stable states – One of several possible outcomes of dynamic modeling of complex systems, i.e., mathematical modeling of dynamical systems over time. Other outcomes include a single equilibrium and oscillations. In alternative stable states, each state is stabilized by feedback mechanisms. The system can, however, shift abruptly between the states by a gradual change in the independent variable when a critical threshold, a tipping point, is reached. Perturbations, i.e., external forces that alter the system structure but are not affected by the system, may also cause a system shift.

Tipping point – In dynamic modeling a critical threshold value of the independent variable where a system shifts to a contrasting state.

Hysteresis – The tipping point where the system shifts from one state to the other differs in value of the independent variable from the tipping point where the system returns to its original state.

Resilience – The ability of the system to withstand a perturbation, i.e., a temporal change of system structure, without changing state.

Introduction

Shallow lakes may change abruptly from lush submerged vegetation and clear water to phytoplankton dominance and turbid water, and vice versa. Such drastic changes not only affect plants but reorganize the entire biotic community and change physicochemical conditions and nutrient dynamics. During the 1970s–1980s, an accumulation of documented cases of structural shifts from a clear to

a turbid state lead to a conclusion that this dynamic is general to shallow temperate waters. These observations were in line with theoretical ecological work, suggesting that ecological systems may shift structure according to alternative stable state dynamics. The theory of alternative stable states in shallow lakes developed in the 1990s, and today shallow lakes are regarded one of the best studied examples of ecosystem with alternative stable state dynamics. In its original version, the model predicts that in shallow lakes two alternative states, a clear state and a turbid state, are possible within an intermediate range of nutrients, primarily phosphorus. The shallow lake ecosystem can shift state, either as a result of a gradual change in nutrient concentrations, e.g., eutrophication, or by perturbations that reorganize the system. Such perturbations can be, for instance, a large-scale removal of submerged vegetation through a storm event, or an altered fish community as a result of a stochastic fish kill or deliberate harvesting.

Theory of alternative stable states

Dynamic modeling of complex systems in some cases shows that the system can exist in two or more alternative stable states. The system is stabilized around these levels by negative feedbacks. A gradual change in the independent variable therefore results in a restricted effect on the state variable, until a threshold value is passed, a “tipping point,” where the system leaves the present state for an alternative state. The change can also be expressed as a system leaving the domain of one attractor and entering the domain of another attractor (Scheffer et al., 2009). As the system shifts from one stable state to the other it will pass an unstable equilibrium, in which the system is affected by a positive feedback that drives the transition. The stabilizing and destabilizing effects of the feedbacks on the system are often illustrated by the heuristic “marble-in-a-cup” model (Figure 1).

The possibility of alternative stable states in ecological systems has been suggested repeatedly through history, for instance, by Lewontin (1969); Holling (1973); Sutherland (1974); May (1977); and Scheffer et al. (1993, 2001). A model for alternative stable states in shallow lakes was presented by Scheffer et al. (1993). According to this model, two alternative states are possible within an intermediate nutrient range. Outside this intermediate range, only the clear state is possible at low nutrient concentrations and only the turbid state at high concentrations (Figure 2).

Empirical support for alternative stable states in shallow lakes

For reasons such as high degree of complexity and large temporal and spatial scale of the system, efficient experimental evidence of alternative stable states in natural ecosystems is scarce. In a critical review of experimental evidence for alternative stable state dynamics in

Alternative Stable States in Shallow Lakes,

Figure 1 Alternative stable states illustrated by the “marble-in-a-cup,” where the marble represents the system and the depth and shape of the “cup” the resilience of the state, i.e., how strong a perturbation has to be to force the system to shift. The lower surface area shows how the ecosystem state varies with the level of conditions. In this relationship, F_1 and F_2 represent “tipping points,” where a gradual change in conditions will cause a shift. Solid lines denote stable states, corresponding to the valleys in the three-dimensional graph above, while the dashed line, an unstable, transient state that corresponds to a hill in the upper graph. Note that alternative states are possible only within an intermediate range of conditions, whereas only one stable state is possible outside this range (Modified from Scheffer et al., 2001).

ecological systems, Schröder et al. (2005) concluded that although experimental evidence for alternative stable state dynamics was predominantly found in laboratory studies, there are no reasons to believe that natural ecosystems should be less prone to this kind of dynamics. Hence, indirect evidence of alternative stable states is in most cases the only realistic aim.

Empirical support for alternative stable states in shallow lakes is generally based on time series, correlational studies, and cross-comparisons. An example of a cross-comparison approach is tests of bimodal distributions among state variables, for instance turbidity, across sets of independent lakes and ponds (Jeppesen et al., 1990; Jackson, 2003).

Alternative Stable States in Shallow Lakes,

Figure 2 Alternative states of turbidity as a function of nutrient concentration in shallow lakes with and without submerged vegetation. The horizontal dashed line denotes a critical turbidity (CT) and “tipping points” (F_1 and F_2 , see Figure 1), where the vegetation disappears with an increase in nutrient concentration and returns with a decrease. Note that outside the nutrient range between F_1 and F_2 , only one of the states is stable, indicated by a dashed part of the line as it passes CT. The arrows show the direction of change in case the system is outside the alternative stable states (Modified from Scheffer and van Nes, 2007).

Examples of lakes that have changed abruptly include the Norfolk Broads in the UK (Moss et al., 1996), L. Veluwemeer (Meijer, 2000) and L. Zwemlust (Van Donk, 1998) in the Netherlands, L. Krankesjön and L. Tåkern in Sweden (Blindow et al., 1993), Tomahawk Lagoon in New Zealand (Mitchell et al., 1988), and L. Christina in Minnesota, U.S.A (Hanson and Butler, 1990). Among these cases, data from L. Veluwemeer are particularly interesting because Meijer (2000) could show that the disappearance and return of submerged vegetation during two shifts – from clear to turbid conditions and back again – occurred at different levels of total phosphorus, the independent variable, which indicated hysteresis in line with predictions based on the alternative stable state theory (Scheffer et al., 2001).

Empirical work on restoration of eutrophicated lakes by means of reduced nutrient loading has provided further support for the presence of hysteresis, as lakes often tend to remain in a turbid state, unless submerged vegetation can establish. Manipulations of lakes in order to reduce the effects of eutrophication have also resulted in improved understanding of fundamental feedback systems that tend to stabilize and destabilize the alternative states (Scheffer and van Nes, 2007). Although the aim of such projects has not been to test predictions generated by alternative stable state theory, they have nevertheless been useful in this aspect and contributed to a rapid development of the ecological theory of shallow lakes (Jeppesen et al., 1998; Scheffer, 1998).

Feedback systems in shallow lakes

Feedback systems play a fundamental role for alternative stable system dynamics, as negative feedbacks stabilize the alternative states and positive feedbacks generate the rapid transition over the unstable state during a shift. If such feedback systems can be documented to have this impact on natural systems, these findings could be regarded as support for the idea that alternative stable states are part of natural ecosystems.

In shallow lakes, several feedbacks have been identified. Of these, some were previously known from the research field of trophic cascades in lakes (Carpenter et al., 1985). This food-chain-based model predicts that altered abundance of top predators such as predatory fish will cascade down the food-chain and influence phytoplankton density and water clarity through effects of intermediate trophic levels such as zooplankton-feeding fish and zooplankton. In shallow lakes, this means that increasing the abundance of predatory fish would promote submerged vegetation through a cascade of decreased biomass of zooplankton-feeding fish, increased abundance of filtering zooplankton, and, finally, reduced biomass of phytoplankton, and thus reduced turbidity. Because reduced turbidity means improved light conditions for submerged vegetation, the plant cover could increase. Increased vegetation and water clarity, in turn, is likely to improve the recruitment of predatory fish, such as pike and predatory perch, and a feedback loop is closed.

The negative relationship between submerged vegetation and turbidity has a central position among feedbacks that are likely to drive the alternative stable state response of the system to environmental change. This and other feedbacks were illustrated by Scheffer et al. (1993) in a graph showing known interactions between expected key compartments of the ecosystem (Figure 3). In this graph, feedback interactions between submerged vegetation and turbidity include two loops: the path over microalgae (phytoplankton as well as epiphytic microalgae) to the upper right (Figure 3) and the path over physical disturbance of the sediment surface to the upper left. In both loops, an increase in vegetation will tend to reduce turbidity, which in turn will promote the vegetation, resulting in a positive feedback. By contrast, in the absence of vegetation cover, a large proportion of the bottom area in a shallow lake can be subject to physical disturbance by waves and currents, resulting in wind-induced resuspension of sediment particles and high turbidity (Bengtsson and Hellström, 1992). The stabilizing effect of submerged vegetation on water clarity thus results from a number of biotic and abiotic mechanisms.

Past and present research

The theory of shallow lake dynamics has developed rapidly in conjunction with a growing understanding of ecosystems, gained from large-scale management projects aimed to reduce the ecological effects of anthropogenic

Alternative Stable States in Shallow Lakes, Figure 3 A conceptual framework of compartments and interactions behind the non-linear dynamics of shallow lakes. The negative and positive signs indicate expected effects by one compartment on the next one in the direction of the arrows. Feedback loops can be identified by following a series of compartments and interactions along the direction arrows.¹ Fish denotes the functional group of invertebrate feeding fish, i.e., feeding on zooplankton or substrate-dwelling invertebrates such as insect larvae, snails, and crustaceans (Vanni, 2002). The dashed line shows the effect of nutrient excretion, an important effect of fish that was not well studied at the time the original figure was presented (Modified from Scheffer et al., 1993).

eutrophication (Hansson et al., 1998; Mehner et al., 2002). The exchange of knowledge has worked both ways, as alternative stable state theory has influenced water management. Besides the applied use of the stable state theory in the management of shallow lakes, the improved understanding of shallow lake dynamics has also contributed to the understanding of ecosystems in general. Alternative stable state dynamics has been proposed to explain observed alterations in a wide range of ecosystems, including for instance rangelands, deserts, ocean communities, and coral reefs (Scheffer et al., 2001; Folke et al., 2004). Among these ecosystems, shallow lakes still remain one of the best studied (Scheffer and Carpenter, 2003).

Lately, the theory of shallow lake dynamics has developed further to include the possibility of more than two stable states (Scheffer et al., 2003), conditions that cause cyclic shifts (van Nes et al., 2007), and the notion that certain cases of apparent alternative stable state dynamics may actually be the result of slow transients from frequent perturbations (van Geest et al., 2007; Scheffer and Jeppesen, 2007). Because of the difficulties to predict a forthcoming shift and to reverse the process in these kinds of systems, there is a need to be able to manage systems so that they are robust against perturbations. For the same reasons, it is important to develop monitoring parameters that provide early warning signals of lowered resistance to perturbations and thus increased risk of a shift to a less desirable state (Scheffer et al., 2009).

AMAZON LAKES

Edgardo Manuel Latrubesse
 Department of Geography and the Environment,
 The University of Texas at Austin, Austin, TX, USA

Introduction

With $\sim 6,200,000 \text{ km}^2$ of drainage area mainly covered by the Amazon rainforest and discharging near 18% of the total flow of fresh water to the ocean, the Amazon fluvial system continues to intrigue naturalists across the world.

Carrying an average water discharge of more than $200,000 \text{ m}^3 \text{ s}^{-1}$ and a sedimentary load that could oscillate between 1 and 2 billions of tons per year to 614 Mt year^{-1} at Obidos, close to the mouth (Meade, 1994; Filizola and Guyot, 2009), the Amazon river is the largest and most peculiar fluvial system of the world with respect to water discharge. The Amazon rainforest, the largest tropical forest in the world, originally occupied more than 5 million km^2 spreading mainly over the Amazon fluvial basin. Humid tropical climate prevails, and rainfall averaging 2,000 mm/year increases in the northwestern direction and in some parts of the Sub-Andean zone to more than 5,000 mm/year. Although the rainforest extends into various countries, $\sim 70\%$ of the total originally forested area was located in Brazil. In reality, the Amazon region is a complex mosaic of different vegetation types, including closed rainforest, flooded forests, campina forests, savannas, bamboo forests, mangroves, montane and sub-montane forests, and liana forests (Murca-Pires, 1984; Witmore and Prance, 1987).

The Amazon fluvial system is characterized for supporting the most extensive floodplain system of the planet comprising a fascinating mosaic of wetlands and floodplain lakes, which sustain a huge biodiversity and have a main role in the emission of carbon dioxide and methane to the atmosphere. In fact, the Amazon fluvial system functions as a major collector to the water and sediments of a large variety of tributaries. Large tributary systems such as the Madeira, Negro, Japurá, Tapajos, Purus River, and others rank between the 20 largest rivers of the planet (Latrubesse et al., 2005; Latrubesse, 2008).

Lakes are a main source of information to understand the quaternary paleogeography and paleoecology of the Amazon as well as key pieces to understand the present-day “physiology” of the environmental system. This chapter focuses on the lake record in the basin since the Late

Cenozoic, attempts to understand the role lakes play in the basin, the main mechanisms generating them, their present distribution, as well as the environmental effects of dams and planned dam construction.

Lakes in the Amazon: When the jungle feeds amazing theories

As in other parts of the world considered “exotic,” by both the scientific community and the public in general, the Amazon has fed several fantastic theories concerning the interpretation of its Late Cenozoic paleogeography. Since the times of the Spanish and Portuguese empires, the fantastic Lake Paraima, supposedly located in northern Amazonia, inhabited in the imagination of conquerors dreaming with the “El Dorado.”

The mythological existence of a huge lake in the Amazon basin has persisted up to recent times. The actions of catastrophic floods as well as the existence of a huge lake and marine incursions were typical theories that produced immediate response in the media and, curiously, in part of the scientific community devoted to natural sciences.

Examples include the 1980’s megafloods theory, which postulated that the southwestern Amazonia was erased by megafloods coming from the Andes in response to the fluvial captures of the large Late Pleistocene Bolivian Altiplano lakes (which extended covering the Titicaca and Salar de Uyuni basins) (Campbell and Frailey, 1984; Campbell et al., 1985) and that a huge lake developed in the Amazon during the Late Pleistocene spreading on the lowlands (Frailey et al., 1988). According to this theory, this lake would have occupied an area larger than the Mediterranean Sea during the end of the Pleistocene, where today we have the richest and most extensive tropical rainforest and the main fluvial network of the planet.

More recently, it was postulated the existence of weak marine transgressions reaching the northern Amazonia during the Late Miocene (Hoorn, 1993). In addition, based on outcrops descriptions of the uppermost levels of the Solimões Formation in Acre territory (southwestern Amazonia), it was proposed that a huge seaway, connecting the Caribbean Sea with the Parana basin all across the South America and crossing the Amazon was installed in the continent during Late Miocene time (Räsänen et al., 1995).

Interestingly, no researcher has found any unequivocal evidence of marine environments in the sediments of the Solimões Formation, the geological unit that is being thoroughly investigated through outcrops and boreholes by geologists, paleontologists, geochemists, and other earth scientists.

While concrete Late Miocene marine environments does not appear in the geological record, some authors have resuscitated and adapted the mega-lake hypothesis in the Amazon, which occurred, instead, during the Middle-Late Miocene. This mega lake, named Lake Pebas, could occupy nearly all the lowlands of the Amazon basin west of the Purus Arch, i.e., roughly all

the lowlands territory located west of Manaus (Wesselingh et al., 2002; Hoorn, 2006).

Very likely, the Pebas mega-lake is “more of the same.” An alternative and more realistic scenario for the Late Miocene of the Solimões Formation consists of a paleoenvironmental model formed by a mosaic of wetlands, active and abandoned fluvial belts, lakes, and floodplain areas (some drier, with development of paleosols); i.e., an area dominated by complex mega-fan hyperarid rivers, floodbasins, and other wetlands areas (isolated swamps and lakes of several sizes) in a mosaic of environments as observed nowadays in several wetlands of the world and somewhat analogous to the Chaco and the Pantanal of Mato Grosso-Paraguay axis today (although the Amazon was wetter during the late Miocene than good part of Chaco) (Latrubesse et al., 2007, 2010).

Where are the lakes in the Amazon?

In spite the fact the Amazon is the largest fluvial basin of the world, located mainly in the humid tropics, the significance and extension of lakes is not so much spectacular as one could expect.

There are no huge lakes in the Amazon. Lakes are restricted mainly to particular geomorphic features in uplands and plateaus or developed as a consequence of fluvial processes in floodplain environments. The largest lakes are in reality flooded fluvial valleys.

A tentative classification of the lake system is shown below. It is possible to differentiate four main categories, including some flooded areas that are not “typical lakes.”

- (a) Lakes developed on older terrains without direct relation to the fluvial systems
- (b) Lakes developed in fluvial valleys and soft quaternary sediments but not directly related to fluvial landforms
- (c) Lakes generated by fluvial processes
- (d) A variety of wetland (and not really typical) “lakes”

Lakes developed on older terrains without direct relation to the fluvial systems

This kind of lake is mainly developed on older Precambrian rocks, affected by intense chemical weathering along the geological time. There is scarce information about the geomorphic processes generating these lakes, usually located on regional surfaces of plantation, often topped with thick laterite crusts, currently undergoing dismantling. Of course, whenever limestone is present, carstic processes can generate a mosaic of small lakes. Lakes can also be generated by “pseudo-carstic” processes, related to the dismantling of the laterite crust or to a more impermeable saprolite associated to the existence of conjugated fractures and the action of subsurface flow of the water table following the regional slope. Similar processes have been studied in some detail by the author in the Cerrado (savannas) area of Central Brazil and in the Cerrado-Rainforest ecotone.

A particular case regards the Carbonatic intrusive rocks which remain as isolated hills above the predominant lowered substrate of the Regional Surfaces of Plantations. A good example is the Six Lakes hills in the northern Amazonia (Amazon State), where the Carbonatitic rocks were deeply altered by more than 180 m of tropical weathering processes and body lakes were generated by dissolution processes.

The quaternary record

The main record of Quaternary palynology of the Amazon basin includes a marine core of the Amazon cone and five points from the following lakes: Carajás (6°S, 50°W), Hill of Six Lakes (0°16'N, 66°4'W), Maicurú (0°30'S, 54°14'W), Laguna Bella Vista (13°37'S, 61°33'W), and Laguna Chaplin (14°28'S, 61°04'W).

In the state of Para, in a little lake on the Carajás Plateau, dry periods were recorded with replacement of rainforest by savanna at 60 kyear, 40 kyear, and 23–11 kyear BP (Absy et al., 1991). All the records show a hiatus in sedimentation between ~23,000 and 13,000 14 C year BP (Carajás), ~32,000 and 12,000 14 C year BP (Pata), or between 25,690 and 17,410 14 C year BP (Maicurú), and 38,600 and 11,030 14 C year BP (Laguna Bella Vista). These hiatus are associated with a lack of deposition of organic material during thousands of years (Ledru et al., 1998) and/or strong erosive conditions. Laguna Chaplin presents a condensed sedimentary or a probably not continued sequence of sedimentation between 31,000 and 9,000 year BP. Presence of tropical semideciduous dry forest at the Cerrado–rainforest boundary in northeastern Bolivia (Bella Vista: Mayle et al., 2000) was documented at ca. 30,000 year BP after which a sedimentary hiatus was recorded lasting until the beginning of the Holocene and tropical rainforest could appear in the area by 2,740 year BP.

This small palynological record together with another locality in alluvial sediments in Rondonia (Catira Site) (Van der Hammen and Absy, 1994) were enough to keep a strong discussion on the Last Glacial Maximum Amazon paleoclimatology and paleogeography of the basin during at least two decades, between palynologists of different groups. However, because of the hiatus existing in the sedimentary record no pollen was recorded during good part of this period. All these studies used similar approaches, consisting of drilling lakes without record and mapping of Quaternary landforms and deposit, i.e., without additional observations or correlations with the sedimentary and geomorphologic units and landscape ecology for each region.

With exception of Hooghiemstra and Van der Hammen (1998), the majority of the palynologists either ignored or misinterpreted the abundant geomorphologic, sedimentologic, and paleo-vertebrates information obtained in the Amazon basin during the last two decades, relying only on the palynological record (see Colinvaux et al., 2000; Mayle et al., 2000; Bush et al., 2004; Anhuf et al., 2006,

among others). Interpretations taking into account just a local record and one “proxy” indicator (pollen) have produced a significant drawback in the understanding of the Quaternary climatic changes of the South American tropics, in special in the Amazon basin.

Lakes developed in fluvial valleys and soft quaternary sediments but not directly related to fluvial landforms

Rounded small lakes, permanent and mainly seasonal, are recorded in Roraima plain, northern Amazonia (Latrubesse and Nelson, 2001). The flat area cribbed by a large number of shallow depressions was affected by aeolian activity during the Late Pleistocene and Holocene. Very dissipated dune fields are recorded in this flat area forming the uppermost units of the Boa Vista Formation (Latrubesse and Nelson, 2001; Teeuw and Rhodes, 2004).

The lakes are circular, pear-shaped, or otherwise rounded in form and small in size – tens to hundreds of meters in diameter. The temporary lakes are affected by frequent grass fires in the dry season. They are consequently bare of woody vegetation, developing only a thin seasonal herbaceous cover. Some of the permanent lakes, however, contain dense communities of rooted shrubs. Depressions with open water or bare damp soil are also distinguishable from the surrounding non-flooded grasslands.

In the Cauamé dune field, the damp depressions are largely elongated and parallel to the prevailing NE-SW wind direction which generated dunes. Closed contours are taken to be the result of deflation behind apices of parabolic dunes followed by incomplete erosional fill-in or a remnant damming effect where younger slip faces once advanced up the deflation corridor of older dunes. In other parts of the sandy and silty realms of the Boa Vista Formation, the depressions are connected by a reticulate system of channels, or are chained like a string of pearls along a single valley. These landforms may be originally circular blow hollows or pans produced by ascendant helicoid winds active in a drier climate, during the hours of greatest solar heating. Circular blow hollows or small rounded pans are active where the water table is low; the soil has a low water retention capacity and sediment is unconsolidated. Circular blow hollows may also have reworked the elongate depressions of the Cauamé parabolic dune field, making them more circular or creating strings of broadened circular depressions along an elongate valley originally entrained by the deflation troughs of a stabilized parabolic dune. Such circular expansions and the development of an interconnected drainage field can explain why the elongate dune axes are difficult to detect in remote sensing products. The blow hollows now occupied by temporary or permanent lakes are inferred to have formed during a Holocene relatively dry phase (middle to lower Holocene) evolving from a mixture of hydro-eolian conditions. Present wet conditions favor dissolution processes on the oxidized sediments of the Boa Vista Formation and maintenance of lakes.

Lakes generated by fluvial processes

The Amazon Rivers can be classified roughly into two main groups due to the sedimentary load they carry and in several subgroups, according to their geological setting and the geomorphology of the channels and floodplains.

Regarding the geologic–geomorphologic context, tropical rivers flowing along fluvial linear belts can be grouped in orogenic mountains belts, Paleozoic and Mesozoic sedimentary plateaus/platforms, Precambrian cratons, lowland plains in sedimentary Cenozoic basins, and mixed terrains (Table 1) (Latrubesse et al., 2005).

Regardless the geology and relief they drain, rivers carrying abundant sediments (white water rivers) are rich in dissolved nutrients, while rivers carrying low quantities of sediments have high dissolved organic carbon and low levels of nutrients and other solutes (e.g., Negro River) or intermediate in solute contents (e.g., Tapajós River). The pH of the white water rivers typically varies between 6.5 and 7 while that of the black water systems varies between 4 and 5. Transparency (Secchi depths) in white water rivers range from 30 to 50 cm while in black rivers it can be up to 2 m (Furch and Junk, 1997). These values can change through the year as a consequence of water depth variations between high and lower water level stages. In terms of suspended sediment concentration white water rivers can oscillate between near 40 mg/l to values as high as 1,500 mg/l during peak discharges in the Madeira River, while than blackwater rivers such as Negro are characterized by values below 20 mg/l.

Floodplain lakes are generated by fluvial processes and are a component of the floodplain morphologies. In the case of the Amazon basin, the huge variety of channel patterns and the existence of complex (in time and space) floodplains induce a mosaic of lakes with large diversity in origin, shape, and functioning.

The floodplain along the Amazon main stem in Brazil (~2,800 km length) occupies approximately 92,400 km², of which 11% was estimated to be covered by 6510 lakes. However, only 10% of the floodplain lakes are larger than 2 km² (Sippel et al., 1992), with small lakes predominating over these landscapes.

Additionally, Sippel et al. (1992) estimated that the lower 400 km of the major tributaries occupy 62,033 km² and that the lake abundance and area of the four main tributaries (Negro, Purus, Japurá, Madeira) spreading in relation to floodplain range from 5% to 12%. For the same area of the Amazon system the mean flooded area between 1903 and 1996 was estimated in 46,800 km², of which river channels water and floodplain lakes comprised approximately 20,700 km² (Sippel et al., 1998).

Hydrologic modeling of the Amazon flooding wave along the main channel suggests that up to 30% of the main stem flow exchange water with the floodplain (Richey et al., 1989). The annual sediment exchange between the main channel and the floodplain on the basis of transport models should be more than twice the flux

Amazon lakes, Table 1 Geological and geomorphological settings for Amazonian rivers and main floodplain lakes types

Subcategory/description	Examples	Characteristic kinds of lakes
A. Rivers generating linear fluvial belts		
A1: Transporting low amounts of sedimentary load		
A.1.1. Precambrian cratonic areas: headwaters in areas of stable precambrian crystalline basement, low relief		
(a) Blocked valley, flooded valleys, very low suspended load	Tapajos, Xingu, Tefé, Coari	Blocked valleys lakes
(b) Wide valleys with islands alternating with narrow reaches with rapids or nodal points, very low suspended load	Negro, Trombetas, Aripuanã	Levee lakes and Igapó forests
A2 Transporting abundant sedimentary load		
A.2.1. Lowland plains in sedimentary Cenozoic basins	Purus, Juruá	Oxbows dominants
Single channel, nonharmonic meanders, muddy banks, high suspended load		
A.2.2. Mixed: Rivers draining mixed terrain		
(a) Platforms + cratons: mainly braided alternating with incised valleys, bed load dominant	Branco	
(b) Orogenic + platforms + cratons (+Lowlands): complex systems, mainly braided tendency, low anabranching, some rivers exhibit rapid alternating with wide alluvial reaches, high sediment load (suspended load dominant)	Madeira, Solimões, Amazon	Levee lakes, round floodplain lakes, island levee lakes, lakes generated by floodplain deltas, scroll lakes, abandoned channel lakes, scarce oxbows.
(c) Orogenic + Lowlands: well-defined headwater areas in orogenic belts and narrow alluvial plains, mixed morphologies (braided/meandering) along lowlands.	Japura, Ica, Mamore.	Oxbows, scroll lakes (Mamoré, Madre de Dios, Beni, Iça, Ucayali). Island levee, rounded floodplain lakes (Japurá)

through the river gauge located at Obidos, in the lower Amazon (Dunne et al., 1998).

However, the Amazon alluvial plain is stated to be not totally inundated during the typical flood season (Tricart, 1977; Iriondo, 1982). Mertes et al. (1996), using Iriondo's interpretation of landforms, estimated that, 40,000 km² of floodplain and 4,000 km² of islands are inundated by direct flooding of the Amazon, between Vargem Grande and Obidos. Some 20,000 km² of deposits of the alluvial belt remain dry or are flooded not by the Amazon but by small tributaries, groundwater seepage, or rainfall (Mertes, 1997).

More recently Hess et al. (2003), using JERS imagery, estimated that 17% of a 1.77 million km² study quadrat in Central Amazonia, which includes the main stem of the Amazon River from slightly downstream of the Napo River confluence to slightly downstream of the Tapajós River, the Negro River south of the Vaupes River confluence, and the lower reaches of the Tapajós, Trombetas, Madeira, Purus, Japurá, Juruá, and Iça rivers, are occupied by wetlands, which were 96% and 26% inundated at high and low waters, respectively. In relation to these figures, about half of the wetland area was occupied by floodplains and channels of the Amazon main stem and major tributaries. Hess et al. (2003) remarked that 70% of the wetland areas are constituted by flooded forest. The mapped classes of vegetation physiognomy and flooding status, however, show large variations because of floodplain geomorphology and with respect to white and black water environments.

Regional biogeochemistry lake analysis had concentrated dominantly along the main Amazon River tract.

An average thermal stratification of 1–3°C occurs daily in varzea lakes with a thermocline of between 2 and 4 m depth while a chemical stratification when water depth is larger than 4–6 m can be found in medium-size lakes (1–10 km²), producing anoxic conditions in the deeper water layers (Furch and Junk, 1997). Amazon floodplain lakes are usually undersaturated in dissolved oxygen and supersaturated in CO₂ because of the high respiration rates in the water column that exceed planktonic gross photosynthesis (Wismar et al., 1981; Richey et al., 1988; Melack and Fisher, 1983). Melack and Forsberg (2001), based on the total lake area of 10,370 km² estimated by Sippel et al. (1992) for the central Amazon floodplain, suggested an average areal production value of 300 t C km² year⁻¹ and estimated that the total gross production of phytoplankton should be 3.1 Tg C year⁻¹ (Tg = teragrams or 10¹² g). Macrophytes are also a main component on the floodplain and abundant in white water rivers lakes. A total regional net production of plants of 113 Tg year⁻¹ could be contributing to the primary production in the Amazon River floodplain in Brazilian territory, between approximately Tabatinga and Almeirim (Melack and Forsberg, 2001). From this total amount 65% is provided by herbaceous macrophytes and 32% by floodplain forest. Peryphitic algae could contribute with ~5% (Melack and Forsberg, 2001).

Nitrogen (N) and phosphorous (P) are adsorbed to suspended sediments of the Amazon River. It was estimated that up to 30% of available P may be adsorbed to clay, and N also can be provided significantly from local source particles (Engle and Sarmelle, 1990). Floodplain lakes lose N and P through several mechanisms such

as deposition of sediments, outflow to rivers and interconnected lakes, and groundwater seepage (Melack and Forsberg, 2001).

Amazon lakes that are closely connected to the channel morphodynamics and flood hydro-biogeochemical inputs are more alkaline and more oxygenated during flood stage. However, the hydro-geomorphologic mechanisms and routing and driving the input of particulate wash load to the floodplain are almost unknown, not just for the Amazon River but for almost the totality of the tributaries.

Nevertheless all the significant data presented above, field information with systematic data on Amazon lakes come from the study of the biogeochemical characteristics of a few lakes – in particular from Lake Calado and Lake Camaleão – a fact also enhanced by the classic biogeochemistry and aquatic ecology reviews by Junk (1997) and Melack and Forsberg (2001).

The lack of detailed geomorphologic mapping and the establishment of distinct relations between hydro-geomorphologic and vegetation units, as well as the use of hydrology without considering the dynamic nature of the physical environment, does not allow a better understanding of the hydro-geomorphologic and ecologic behavior of the floodplain and other flooded areas, including lake systems. A multidisciplinary approach strongly based on fluvial geomorphology and detailed hydro-geomorphologic mapping become necessary. Lake morphology and behavior are related to the fluvial regime and to the geomorphologic style of the rivers, as well as to the paleohydrologic landform heritages recorded in the floodplain and lower terraces, which are also related to the floodplain sedimentary architecture.

The Amazon floodplain lakes can be classified as a function of the genetically related fluvial processes, with the following main types:

- (a) Lakes related to lateral channel shifting: lakes in abandoned channels tracts, oxbows (lakes or swamps depending the degree of siltation), composite chained oxbows, scroll bars lakes, composite scroll bars lakes, lakes in lateral accretion processes attaching islands to the floodplain
- (b) Lakes generated by landforms built by vertical accretion processes in the main channel and by floods on the floodplain, affecting the floodplain and tributaries of rivers: round floodplain lakes, lakes generated by floodplain deltas, levee lakes, island levee lakes, blocked valley (Ria Lakes)

Lakes related to lateral channel shifting

Oxbows (lakes or swamps as related to the degree of siltation). Oxbow lakes are typical elements of meandering floodplains. In the Amazon basin, there is a considerable number of tributaries which show meandering patterns, and, in all of them, oxbow lakes are the dominant lacustrine landforms.

Rivers with abundant sedimentary load draining the lowlands (Jurua, Purus, Javari), as well as mixing terrains

(orogenic areas and lowlands), such as Mamore, Madre de Dios, Beni, Ucayali, Iça, among others, show a variety of meandering patterns. In these rivers, it is possible to identify several generations of abandoned meanders in several stages of siltation in the floodplains and swampy areas, occupying old meanders in the lower Holocene-Late Pleistocene terrace (Figures 1 and 2a). Vegetation is a main indicator to determine the level of evolution/siltation of these lakes.

The typical channel pattern of lowland tropical rivers, such as Jurua and Purus, is that of single sinuous channel with medium to high sinuosity occurring in between shorter straight reaches. The meanders are compounded and asymmetric, and several reaches exhibits irregular and tortuous pattern. Sinuosity in the meandering reaches varies, with values as high as 2.7 and width-depth channel ratio values mostly between 17 and 27. Because of the irregular and tortuous channel pattern, meander geometry shows a wide range of values. Suspended load is dominant, reaching 98% of the total sediment load (Gibbs, 1967; Mertes and Meade, 1985). Meanders are abandoned mainly by neck cutoffs and lateral rates of channel migration are low. Radiocarbon dating in fluvial deposits indicate that during part of the Late Pleistocene (Middle Pleniglacial to early upper Pleniglacial) and Holocene, the lowland rivers suffered important paleohydrological changes, although meandering patterns were always dominant and oxbow lakes a characteristic of these kind of rivers (Latrubesse and Kalicki, 2002; Latrubesse and Rancy, 1998, 2000).

Oxbow lakes are very rare in the Solimões-Amazon main stem and in the Madeira River because of the tendency of the channel to generate an anabranching low sinuosity pattern. However, it is possible to identify a big oxbow lake north of Xibeco which is located on an avulsed fluvial belt of the Solimões main stem (Mertes et al., 1996).

Scroll bar lakes (simple and compounded). These kinds of lakes are generated in between scroll bars, in a meandering scrolled floodplain. The lakes are elongated, usually intermittent and dependent on the flood dynamics. Scroll bars lakes are mainly found in meandering tributaries draining mixed terrains such as the Mamore, Beni, Madre de Dios, Ucayali, and Iça rivers, for example. Compared to the lowland tributaries (Purus, Jurua, Javari), these rivers have more harmonic meanders, show more lateral activity and scrolled floodplains, and transport relatively more bed sandy load. However, scroll bars lakes can also be found in large and complex rivers with tendency to anabranching, such as the Solimões-Amazon. The Upper Solimões have a tendency to anabranching and to generate complex multichannel tracts like the meanders from Iquitos to Tefe (along a reach ~1,100 km in length). The channel-dominated floodplain is a complex mosaic of fluvial forms, including younger channels, active sandbars, islands, levees, scroll-dominated plains, and abandoned belts. The curvature of the scroll morphology suggests that generation by secondary channels or

Amazon lakes, Figure 1 Location map. Numbers indicate the location of the chapter's figures.

paranás are the main factors in the genesis of these deposits and morphologies (Mertes et al., 1996; Latrubesse and Franzinelli, 2002). Specifically, scrolls are mainly generated by lateral activity of the paranás (Figures 1 and 3b). Elongated, narrow and arched lakes occur in the swales. In some places, these lakes may have a finger-like shape, as a result of the ridge and swale topography and the different angles of intersection between the scrolls. With respect to the scrolls, these relate to an upper point bar, and are typically composed of fine sediments.

Lakes in abandoned channels tracts. Abandoned channel tracts are associated to avulsion processes, which are particularly related to sunken tectonic blocks or other areas of tectonic instability, as well as to channel instability in flooded basins where rivers shows a tendency to generate vertical accretion floodplains. In the Amazon, these lakes are mainly associated to sunken prismatic tectonic blocks. These “lakes” are in reality a complex relation of pounded areas occupying abandoned channels and floodplain channels connections and, depending on the flood stage, many of them can behave as lakes or have a fluvial tendency to interconnecting and draining away the floodplain. Due to their channel morphology and well-developed banks, these lakes are rather stable in area.

In Brazil, we identified three main areas with this kind of lakes. The first one is located in the lower reaches of the Moa River, a tributary of the Jurua River in the Brazilian southwestern Amazonia (Figures 1 and 2b).

The second area (and good example of a lake developed in abandoned channel) is the confluence between the Japurá and Solimões rivers, where the Reserve of Sustainable Development of Mamirauá is located.

The third one is associated to a sequence of neotectonic blocks affecting the Solimões from Xibeco to the Purus River confluence (Figs. 1 and 3b). Avulsion on the Solimões River, north of Xibeco, has been described by Mertes et al. (1996), while Latrubesse and Franzinelli (2002) found a large abandoned belt of the Solimões River upstream of the confluence with the Purus. At present, the Solimões River flows through the north of this area, close to the northern border of the V-shaped block and near the contact with the upper tertiary Solimões formation. The abandoned belt cuts the previously deposited sediments of the impeded floodplain that currently includes a large number of lakes. It is evident that the Solimões River avulsion caused abandonment of approximately 160 km of the river reach. Radiocarbon dating of the sediments of the Solimões alluvial plain, close to the mouth of the Purus, yielded an age of 1,000 years BP.

In Amazon lowland rivers such as Purus River, older meandering belts abandoned by avulsion were recorded during the early-middle Holocene (Latrubesse and Kalicki, 2002) which indicate that during this aggradation phase, oxbows, as well as lakes in abandoned meandering channel tracts were the main elements of the floodplain. In fact, many of these areas are now occupied by swampy environments.

Amazon lakes, Figure 2 (a) Purus River upstream Boca do Acre city. The tortuous meandering pattern generates oxbow lakes (1). Older swampy areas occupy paleomeanders (2) up to ~7 kyear BP while less spread and shallow swampy areas in old meander scarres (3) can be also founded on the Late Pleistocene terrace (~60–20 kyear BP). (b) Lakes occupying abandoned channels by avulsion in the Moa River floodplain (4). Some of the abandoned channels can be partially and episodically reactivated and fed by floods.

The Ucamara depression in the Peruvian Amazonia can also be used as a good example of lake generation in abandoned channel belts because in this area abandoned meander belts of the Marañón and Ucayali Rivers have been described (Dumont and García, 1991).

Lakes generated by vertical accretion processes in the main channel and by floods on the floodplain (affecting the main river floodplain and tributaries):

These kinds of lakes are generated by flood dynamics mainly in anabranching low sinuosity rivers such as the Solimões-Amazon, the Madeira, and the Japurá (Latrubesse, 2008). The floodplain of these

rivers presents an impeded floodplain alternating with a channel-dominated floodplain as described by Latrubesse and Franzinelli (2002) in the Solimões-Amazon main stem. The impeded floodplain has a complex origin. Its sediments originated in several Holocene temporal stages, but overall, there is a tendency for vertical accretion in this geomorphic unit. Round floodplain lakes, levee lakes, island levee lakes, and lakes generated by floodplain deltas are typical features of this geomorphic unit.

Levee lakes. Large levee complexes lay on the sides of the channels and their development depend on the

Amazon lakes, Figure 3 (a) Amazon river at the confluence with Tapajós River. Note the abundance of blocked valleys (1), rounded lakes in an impeded drainage floodplain (2), the spectacular levees confining the river flow along a narrow corridor inside a water saturated floodplain (3), the large islands and island lakes (4), and delta systems entering in the floodplain lakes (5). (b) Solimões River at the confluence with Purus River. Note the large alluvial belt of the Solimões river abandoned by avulsion (6). The area is located in a neotectonic prismatic block. A large quantity of small rounded lakes form the impeded floodplain unit while secondary more sinuous channels generate small lakes in a scrolled topography (7) and small lakes, mainly temporary, can be founded inside the islands (4). Levees are present (3) and sedimentation of the floodplain blocked several tributaries generating blocked valley lakes (1).

hydraulic geometry of the channel section and channel stability. Low anabranching rivers transporting abundant sedimentary load generate important levee complexes. In the Solimões-Amazon, these complexes increase in importance downstream Manacapuru (Figures 1 and 3a). The height of the levee complex typically varies between 1 and 10 m above the low water level of the river. The sediments characteristically are composed by the intercalation of sandy and fine deposits. Nevertheless, the existence of a sandy platform at the base of the levee is common. The amount of fine sediment and the

intercalation of fine and sandy deposits increase upward and highly bioturbated muddy sediments occur at the upper levels as a consequence of the vegetation colonization of the levee. For example, in the Solimões River at Iranduba, upstream of Manaus, the levee complex is approximately 22 km in length and up to 4 km in width, and the contact between the fluvial sediments and the banks of the Cretaceous sedimentary rocks of the Alter do Chão Formation are visible.

Likewise, levee lakes are also very important features in rivers carrying today a small amount of sedimentary

load. As described in the Negro River by Latrubesse and Franzinelli (2005), important paleohydrological changes happened in the Amazon basin during the Late Holocene. Many rivers draining cratonic areas, such as the Negro, the Tapajos, the Xingú, the Trombetas, and the Aripuaná, exhausted their yield of fine sediments, aborting the development of floodplains in recent times. These rivers carry today an insignificant quantity of suspended load and behave as blocked valleys having almost a lacustrine dynamic in their lower reaches. Huge and spectacular levees can be observed inside huge flooded valleys, covered by Igapó forest (Figure 4). In between these levee complexes, lakes, interconnected with the other elements of the floodplain during floods, are present.

Round floodplain lakes and lakes generated by floodplain deltas. Both kinds of lakes are characteristics of the impeded floodplain. As mentioned before, the impeded floodplain is a widespread unit characterized by a number of round or irregularly shaped lakes on a very flat surface, dominated by low sinuosity anabranching rivers such as Solimões-Amazon, Madeira, and Japurá (Figures 3a and b). Some of these lakes are connected to the main system by small channels. Others, however, are isolated from the main channel. At times, this unit is

inundated by annual floods, although it is not totally flooded every year. This unit resembles local flood basins formed by gray to gray-green muddy sediments. Orange or yellow bioturbated mottled sediments are also frequently found, as opposed to primary sedimentary structures. In several places, it is possible to find remnants of tree trunks, some of them in “life” position. In certain circumstances, trunks were associated with strata primarily composed of leaves and stems. Radiocarbon dating of trunks from the basal beds of the Careiro Island, in the Solimões-Amazon River, indicated ages ranging between 300 and 2,500 years (Latrubesse and Franzinelli, 2002; Absy, 1979; Sternberg, 1960).

A conspicuous quantity of round lakes are recorded in the sunken tectonic block of the Solimões River upstream the Purus-Solimões confluence as described before (Figure 3b). The increment in the numbers of lakes was also noticed by (Sippel et al., 1992), who, however, did not identify the cause of this increment which is as a consequence of avulsion activity and channel abandonment of the Solimões River in this area (Figure 3a).

Although the sediments of the impeded floodplain originated in several temporal stages, there is a tendency for vertical accretion in this geomorphic unit. Levees played an important role in alluvial sedimentation. As normally

Amazon lakes, Figure 4 Spectacular levee development in the Aripuaná River, a main Brazilian tributary of Madeira River. The river carries today a very low amount of suspended load and functions as a blocked valley system with a lake dynamic (1) behind the levees (2) which confined the channel.

happens, the distal levee areas consists of more depressed areas that, in some cases, are covered by tropical alluvial plain vegetation. When levees are broken during floods, the distal levee areas become swampy or flooded. Splay-like systems or minor channels develop, connecting the main system with the back-flooded areas. As the splay deltas coalesce with other levees, these depressed areas are constrained and limited, generating lakes.

As expected, these lakes are shallow and their depths correspond to the maximum heights of levees and thickness of the splay deltas. The vegetation (including arboreal physiognomies) frequently covering a flooded area has resulted in several profiles containing large quantities of organic strata at the base of the sedimentary column. Organic strata are formed by detritus such as stems and leaves marking the original soil/substrate of the newly generated lake or flooded area. While low energy sedimentation is in process, the dead flooded trees are buried in a vertical position.

Additionally, recent sediment of the present-day channel occurs locally on the impeded floodplain, indicating that the modern alluvial system is actively blanketing and reworking the impeded floodplain deposits.

Island levee lakes. The islands in large anabranching low-sinuosity rivers such as the Solimões-Amazon and the Madeira usually have a “sandy core” formed by sandy bar deposits (Figures 3a and b). The creation of an island includes two distinct processes: (1) the generation of a sandy bar or sandy core of the island (on – or without – a “skeletal base” of impeded floodplain deposits), and (2) a mix of vertical and lateral accretion processes associated with main channel dynamics. However, in some cases, the base of the impeded floodplain is not found, resulting in a base composed of channel sandy bar. The typical evolution of an island begins with the development of large channel bars mentioned above. These sandy units are then stabilized by pioneer vegetation. The original bar takes a hexagonal shape. At a later stage, levees begin to develop and to characterize the mix of vertical and lateral accretion stage of the island. The vertical accretion processes build an emerging area frequently flooded during the annual floods. The island surface presents a ridge-and-swale topography similar to that of the scroll-dominated floodplain, but with straighter scroll morphologies. The upstream ends of the islands have abrupt erosive banks up to several meters high during low water level. On the other hand, the low sinuosity of the main channel favors the development of low sinuosity scroll/levee morphologies. Thus, an undulated landscape with a straight ridge-and-swale topography develops on the island surface. A few small elongated lakes persist in the swales in which fine sediments are deposited until the lakes become filled. Because of the smoothing of the older core ridges in the island, a large “inland” rounded to digitate lake can appear in the core of the islands. Lake Camaleão, a systematically studied lake of the Amazon floodplain, is a good example of an island levee lake.

The persistency through time of this kind of lakes varies in each fluvial system or fluvial track. For example, ^{14}C dating of sediments in the large Careiro Island (ca. 415 km²) which contains lake Rei indicates that the island was almost a continuous channel feature for more than 2 kyear (Sternberg, 1960; Absy, 1979; Latrubesse and Franzinelli, 2002).

Blocked valley (Ria lakes). Blocked valleys are characteristic of the Amazon basin and probably in no other fluvial basin of the world this kind of geomorphic features are more spectacular than here (Figures 3a and b).

Blocked valleys or “ria lakes” were interpreted to be formed when valleys scoured during periods of lowered sea levels of the Late Pleistocene related to a sea level ~100 lower than today which were subsequently flooded during the Holocene (Sioli, 1984; Irion, 1984; Irion et al., 1997) or related to tectonic effect in prismatic sunken blocks (Dumont, 1993; Iriondo, 1982) but in concrete they are related to the difference in sediment transport and energy between a main system carrying abundant sedimentary load developing a significant floodplain blocking the mouth of a tributary which has a lower energy and a lower sediment discharge than the collector system. The eustatic effect is not necessary to develop this kind of lakes. Because of the low slope that characterize large rivers, adjustments in the longitudinal profile as response to eustatic changes are just transmitted some hundreds of kilometers upstream from the river mouth. In the Amazon River water slope is extremely low, oscillating from ~6 to 3 cm/km and blocked valleys are recorded in regions that were without direct effect of sea-level changes. Blocked valleys are founded very far from the ocean, in areas which were not affected by sea-level changes such as the Ucamara depression in Perú, the upper floodplain of the Araguaia River (tributary of the Tocantins), and others.

Additionally we need to take account that the sea level was changing along the glacial cycle and not permanently located to 100 m below present sea level. In this case the adjustments along the longitudinal profile were dynamics and would not be only related to the lowermost level reached by the marine regression as claimed by Sioli (1984) and others when comparing the ~100 m depth channels of the Amazon or the ~80 m of the Negro river near Manaus.

Lakes in blocked valleys have “clear” and “black” waters because the production of sediments of the blocked tributaries basins covered by rainforest is very low.

Other big rivers where almost blocked by the Solimões-Amazon as well. For example the lower Negro was partially blocked by the Xiborema levee complex but the huge discharge of the Negro which is constrained by geologic effect in the lower reach permit that the river reaches the Solimões (Latrubesse and Franzinelli, 2005). The Tapajos River, which has less discharge than the Negro, suffered strongly the blocking effect because of the development of a very stable levee complex on the right side of the Amazonas River. The huge Tapajos valley is flooded

and the river connects to the Amazon by a small and narrow mouth. Sediments of the Amazon transfer behind the levee, as described for delta lakes entering the water saturated floodplain, with the only difference that here they enter in a huge blocked fluvial system, the Tapajos, forming a delta system as earlier described by Sioli (1957, 1984). Because ria lakes are in fact blocked fluvial valleys, w/d ratios are in relation to the original morphometry of the former fluvial channel and floodplain. Depth can be significant and may reach more than 10 m in some systems along the original thalweg of the former channel. The Lake Calado close to Manacapuru is the most limnologically studied blocked valley lake. As hydro-geomorphologically expected in these kinds of lakes, limnological studies identified that the Calado water level oscillates near 10 m and local runoff, direct rainfall and seepage are responsible for ~78% of the water input (black water) while contributions from the Amazon River floods are not significant and restricted to the “confluence” zone of the tributary ria lake with the Amazonas floodplain (Lesack and Melack, 1995).

Reservoirs in the Amazon basin

Near 93% of the electric power of Brazil is generated by over 400 large and medium-size power dams. In the Amazon basin, dams are concentrated in the Brazilian territory (Table 2), with two large reservoirs located in the Amazon fluvial basin: Balbina, built on the Uatuma River in 1987 to supply power to Manaus, and Samuel, also built on a relatively small size river, the Jamarí, a tributary of the Madeira River. Balbina has flooded 2,400 km² of rainforest to produce 250 MW, enough for only half of the city's present needs. Balbina is a good example of an engineering and environmental disaster because of the large impacts and the small hydropower production.

Other dams built in the Amazon rainforest during the last decades are in the Tocantins River basin. This basin has experienced a huge human pressure during the last decades since the construction of Tucuruí dam and the expansion of the agricultural and cattle ranch frontier along the savannas (Cerrado) of Central Brazil and the

development of the Tocantins State. The Tucuruí Hydropower Complex, completed in 1984 in the lower Tocantins River, was the first large dam built in the Amazon rainforest for hydropower generation but today six large dams exist on the Tocantins River.

The role of large dams in the generation of green house gases (carbon dioxide and methane) is remarkable. Estimates of emissions during the first decade after reservoir filling for the year 1990 (i.e., the baseline year for national greenhouse gas inventories under the climate convention) totaled ten million tons of carbon for the existing dams in Brazilian Amazonia: 2.55 at Tucuruí, 6.43 at Balbina, 1.13 at Samuel, and 0.01 at Curuá-Una while methane emissions should be 90,000 t and 140,000 t in Tucuruí and Balbina, respectively (Fearnside, 1995).

Feasibility studies are currently being carried out on the Xingu, Madeira, Tapajós, Teles Pires, Trombetas, and Araguaia rivers in the rainforest environment and the Amazon-Cerrado ecotones. Without exception, all the related projects are marked by severe social, economical, and environmental controversies.

Particularly controversial are the dams in the Madeira and Xingú rivers.

With 32,000 m³/s of mean annual discharge, the Madeira is the fourth largest river of the world in water discharge and the most important tributary of the Amazon. The Upper Madeira developed some of the world's most spectacular sequence of rapids between Porto Velho and Guajará Mirim (Figure 5).

Two hydroelectric dams currently under construction are Jirau and Santo Antonio, on an uneven stretch of the upper Madeira River, in the western Brazilian State of Rondonia. These complexes, part of a larger four-dam cascade to generate electricity and permit navigation along the Peruvian and Bolivian tributaries, could have a potential energy production of 3,300 and 3,150 MW, respectively, and a cost of approximately 12\$ billions. To provide a scale of the significance of this system, we can mention that at the dammed area, the Madeira River transports more water discharge than that originally transported by the Yangtze River at the largest dam of the world: Three Gorges.

Amazon lakes, Table 2 General data of the main dams of the Brazilian Amazon basin

Dam	Latitude	River	Year of construction	Biome	Power (MW)	Reservoir area (Km ²)	Estimated cost
Tucuruí	03°45'S; 49°40'W	Tocantins	1984	Rain forest	4,240	2,430	US\$5.5 billions
Samuel	08°45'S; 63°28'W	Jamari	1988	Rain forest	217	645	US\$836 millions
Balbina	2°26'24" S; 58°15'0" W	Uatuma	1987	Rain forest	218 planned but 112.2 produced	2360	US\$1000 millions (estimated)
Curuá Una	2°50'S; 54°18'W	Curuá Una	1977	Rain forest	40	72	–
Santo Antonio and Jirau	8°49'; 63 58 and 9°19'S; 64°43'W	Madeira	Under construction	Rain forest	3,150 and 3,300 respectively	271 and 278 respectively	US\$12 billions
Belo Monte	3°26'S; 51°36'W	Xingú	Put out to tender	Rain forest	11,000	516	US\$11 billions

Amazon lakes, Figure 5 Teotônio Rapids, located in the area of influence of the Madeira's dams, upstream Porto Velho city. The Madeira generated at these reach the largest rapids of the world in terms of water discharge. This sequence of spectacular rapids (Jirau, Teotônio, Santo Antonio) will disappear because of the dam's construction.

From a hydro-geomorphologic point of view, the Madeira River offers a tremendous challenge for river management and dam building because of the inexistence of gorges or abrupt relief. The river valley cuts a low landscape and a lower terrace and at this reach the mean annual discharge is more than 22,000 m³/s with peaks that reach more than 80,000 m³/s. The suspended sediment transport is ~280 Mt (Filizola and Guyot, 2009). Because of the insignificant relief, mistakes in the project can produce huge environmental impacts due to the permanent flooding of the lower terrace, generating swamps in both sides of the river (in Bolivian and Brazilian territory), as well as affecting the longitudinal profile of the tributaries, what would transmit environmental impacts to their floodplains. The decline of sediment availability downstream the dams and high environmental impact in the lower Madeira and lower Amazon system are expected.

In the Xingu River, Belo Monte dam, first proposed in 1975 by Eletronorte (a state-owned utility company) and originally consisting of two dams (Babaquara and Kararaô), is one of the recurrent projects proposed for hydropower generation since the 1970s.

The whole complex would have five generating plants along the Xingu River with the capacity to generate 14,700 MW (Fearnside, 1995). In fact, Eletronorte suggested to build up to four additional dams (Altamira, Ipixuna, Krokaimoro, and Jarina), flooding a total area of 22,000 km² (Fearnside, 1995, 2005).

Recently, the project was reevaluated and redesigned for a reservoir area of 440 km² (Carvalho, 2006) and an installed capacity of 11,181 MW. The estimative cost of the reservoir would be at least \$12 to \$18 billions. However, the Altamira/Babaquara Dam which should be located upstream to increase the power generation at Belo Monte would flood an area of 6140 km² (Fearnside, 2006).

Acknowledgment

I specially thank Dr. Ph. Fearnside for providing valuable information on dams in the Amazon basin.

Antarctica

The Antarctic continent, including its ice shelves, has an area of 13.8 million km², about half the size of North America and 1.3 times the size of Europe. It is also the highest, windiest, coldest, and driest of the continents. Almost the entire land surface of Antarctica is covered by a vast ice cap, with an area more than six times larger than its counterpart in Greenland. In places, the ice cap is 4 km thick. Here, summer temperatures rarely get above –20°C and monthly means fall below –60°C in winter. Vostok station, at 78°South holds the record for the lowest ever temperature recorded at the surface of the Earth (–89.5°C). On the coasts of Antarctica temperatures are generally close to freezing in the summer months (December–February), or even slightly positive, particularly in the northern part of the Antarctic Peninsula. During winter, monthly mean temperatures at coastal stations are generally between –10°C and –30°C, but may briefly rise toward freezing when winter storms bring warm air toward the Antarctic coast. With average precipitation (as snow) amounting to only 100–150 mm of water equivalent a year the area is technically a desert, although

the ice cap contains almost 70% of the world's freshwater and 90% of the world's ice. The surrounding ocean freezes in winter to cover an area 1.5 times the size of the continent.

Only 0.32% of the Antarctic continent is ice-free. This mainly consists of mountain peaks (nunataks) protruding from the polar ice cap. However, 1–2% of this includes coastal oases that have been exposed, both through postglacial retreat of the ice cap and isostatic rebound of the Earth's crust following the most recent deglaciation. The largest oasis is situated near the coast of the Ross Sea and is known as the McMurdo Dry Valleys. Other large oases are found in eastern Antarctica including the Vestfold Hills, Larsemann Hills, Bunger Hills, Schirmacher Oasis, Syowa Oasis, and on the Antarctic Peninsula at Ablation Point on the east coast of Alexander Island. There are also numerous islands surrounding the Antarctic continent south of 60°S. Most lie close offshore but a few form discrete archipelagos 100–500 km from the mainland (e.g., South Shetland Islands and South Orkney Islands), some are active volcanoes (e.g., Deception Island, Ross Island, and the South Sandwich Islands) while others are isolated, far out in the Southern Ocean (e.g., Macquarie Island, Heard Island, and Amsterdam Island). Collectively the ice-free coastal oases of the continent and the ice-free ground on the islands support much of the well-known fauna of seals, penguins, and marine birds, as well as a variety of macro flora including higher plants, mosses and lichens.

Antarctic lake types

Given the limited area of ice-free ground, it is perhaps surprising that the Antarctic continent and subantarctic islands (loosely defined as those areas south of 60°S latitude) are home to one of the most diverse and interesting lake districts on Earth. Indeed, even though the Antarctic is the repository of more than 70% of the world's freshwater, less of it is available in liquid form than on any other continent. Nevertheless, water bodies that contain liquid water for at least part of the year are a common feature of the Antarctic landscape. This is because water accumulates in areas where solar radiation and advected heat promote melting. This process is self-perpetuating since, as bare ground is exposed, its albedo drops and more radiation is absorbed. As a result, liquid water is not uncommon on ice-free ground. However, liquid water also occurs on and beneath the glaciers and ice sheet. Wherever this water accumulates lakes and ponds are formed. Below we describe some of the different lake types found in Antarctica.

Lakes in ice-free areas

Among the most intensively studied Antarctic lakes are those that occur in the ice-free oases on the edge of the continent such as the Vestfold Hills, Larsemann Hills, and McMurdo Dry Valleys, and those on the maritime and subantarctic islands such as Signy Island and King

George Island. These range in size from small ponds to lakes of $>10 \text{ km}^2$, in depth from few mm to over 300 m, and in age from a single summer to several full glacial cycles. Those that contain liquid water throughout the year, with either seasonal or perennial ice insulating the water against heat loss and complete freezing, are generally referred to as lakes while those that freeze to the base during winter (typically $<2 \text{ m}$ deep) are referred to as ponds. Most of these lakes postdate the Last Glacial Maximum, between 25,000 and 18,000 years ago, when the ice sheet expanded over many of the coastal oases and across the continental shelf. As this ice receded it exposed depressions in the landscape, formed either from glacial erosion or the deposition of terminal moraines, or as a result of folds and depressions in the underlying geology. These depressions filled with water, the lakes were colonized by a range of organisms, and began to accumulate the sediments that today reveal their history. In some rare areas lakes survived intact through the Last Glacial Maximum, for example, the Larsemann Hills, Schirmacher Oasis, and Bunger Hills; and in the McMurdo Dry Valleys, lakes have occupied some of the valley floors in different configurations for over 300,000 years, their depth and area being determined by the spatial extent and thickness of bounding ice sheets and glaciers. Lakes on the subantarctic and peri-antarctic islands are often of Holocene age, formed during the retreat of local ice masses and cirque glaciers. Some of the islands further north such as Macquarie Island may have escaped extensive glaciation and are likely to contain older lakes.

Many of the lakes at lower altitudes in ice-free areas are below the Holocene marine limit ($<40 \text{ m}$ in the Antarctic Peninsula, $<8 \text{ m}$ in the Larsemann Hills) and have formed in depressions emerging from the sea as a result of postglacial isostatic rebound (Figure 1a). Conversely, those at higher altitudes and above the Holocene marine limit have had no prior hydrological contact with the ocean. Where the lakes have no surface outflow they are referred to as closed (or endorheic) lakes. Some of these closed lakes have subsequently experienced an excess of evaporation over precipitation and have gradually become saline. Examples of these are found in the Rauer Islands (Figure 1b), Vestfold Hills, Windmill Islands, and McMurdo Dry Valleys. Some saline lakes become stratified for part of the year (monimictic) and others are permanently stratified (meromictic), retaining a trapped layer of salt water below their fresh surface waters. Lakes that have outflow streams are classified as open lakes; these are typically freshwater and do not accumulate salts to the same degree. Both types of lake are common in Antarctic oases such as the Larsemann Hills, Vestfold Hills, Schirmacher Oasis, Bunger Hills, and on the Antarctic Peninsula (Figure 1c) and maritime antarctic islands.

Epishelf lakes are formed in marine embayments or fjords, dammed by advancing glaciers and ice shelves and have been described in the Bunger Hills, Schirmacher

Oasis, Amery Oasis, and Antarctic Peninsula. In these lakes the marine water is replaced over a period of time by fresh melt water from glaciers and snow. In some cases the bounding ice forms an incomplete seal and a hydraulic connection to the sea persists under the ice shelf or glacier, sometimes more than 100 m below sea level. When this happens the epishelf lake becomes stratified with freshwater overlying a layer of dense saline water. Where the seawater flows freely under the ice shelf or glacier a tidal regime can be maintained, which is revealed at the surface by, often characteristic, tide cracks that appear in the ice around the edges of the lakes. Two examples of tidal epishelf lakes are found on the coast of Alexander Island (Moutonnée Lake (Figure 1d) and Ablation Lake). Other epishelf lakes are currently isolated from the sea, formed during earlier periods of relative sea-level rise, lifting grounded ice masses and allowing sea water to penetrate into the lower part of the water column, or connected to marine waters only during periods of reduced freshwater input.

Lakes beside, on, and under the ice

Liquid water is also found against glacier fronts or beside ice shelves, in depressions on glaciers, ice sheets, and ice shelves, and beneath the Antarctic ice sheet. These are called epiglacial, supraglacial, and subglacial lakes, respectively.

Epiglacial lakes are usually formed in depressions at the boundary between areas of rock and ice and are often perennially ice-covered. They are found around the edges of Antarctic nunataks, at the snouts of glaciers, and along the grounded edges of glaciers and ice shelves. They are among the most common lake types in Antarctica and can be found deep in the interior of the continent to within a few hundred kilometers of the pole. Along the Antarctic Peninsula and on the subantarctic islands the lakes are often ice-free in summer with snowmelt from the rock catchment, and meltwater from the bounding ice both contributing to the standing body of liquid water. Although mainly seasonal, epiglacial lakes may persist for several years, often with frequent changes in water level and morphology on account of glacial movements and changing meltwater inputs. Some, such as Lake Untersee in East Antarctica, are older than 500 years. Further south, they can be permanently ice covered with occasional moats forming as a result of advected heat on the landward sides melting the lake ice during warmer summers. This glacial meltwater can also occasionally flood the surface and refreeze restoring the “flat” surface of the lake as seen at Edge Lake in Davis Valley in the Dufek Massif. Some of the largest epiglacial lakes are found at glacier fronts in the McMurdo Dry Valleys (e.g., Lake Fryxell and Lake Hoare, Figure 1e).

Supraglacial lakes are found on the surface of the ice sheet, glaciers, and ice shelves and range from cryoconite holes, less than a meter across, to meltwater lakes that can extend to several square kilometers. They are typically seasonal, forming during the summer melt (Figure 1f).

Antarctic Lakes, Figure 1 Photographs showing selected Antarctic lake types, (a) an isostatically uplifted “isolation basin” lake on Pourquoi-Pas Island, Antarctic Peninsula (in the foreground), (b) a hypersaline closed basin lake in the Rauer Islands, East Antarctica, (c) an open basin freshwater lake on Horseshoe Island, Antarctic Peninsula (d) Moutonnée Lake – an epishelf lake on Alexander Island, formerly a marine basin, now a stratified lake impounded by George VI ice shelf (in the foreground), (e) epiglacial Lake Hoare in the McMurdo Dry Valleys, and (f) ephemeral supraglacial lakes on the Sörsdal Glacier in the Vestfold Hills, East Antarctica, each of these lakes is approx. 250 m wide.

The larger meltwater lakes occupy depressions formed by the stress of moving ice and areas that will later become crevasses. Cryoconite holes are small cylindrical depressions in the ice, likely formed by the presence of wind-blown material including mineral sediments and desiccated microbial mat that provide small concentrations of advected heat sufficient to melt down into the ice. The subsequent growth of microbial mats in these depressions can often serve to enhance this process and so a more-or less self-maintaining ecosystem is formed containing liquid water and supporting a surprising diversity of

biological communities. It is not surprising, therefore, that they have been proposed as one of the main refugia for the eukaryotic biota in the controversial Snowball Earth hypothesis, when the Earth underwent extreme freeze-drying events between 750 million and 580 Ma ago. Kettle ponds can also form in depressions on ice-cored moraines where the rock promotes the melting of ice through reduced albedo and advected heat. Many of these contain diverse and productive biological communities, the most well-known examples being found on the surface of the McMurdo Ice Shelf at Bratina Island.

Subglacial lakes, rivers and wetlands, deep beneath the Antarctic ice cap were revealed by airborne radio echo sounding in the 1970s. These lakes, which lie up to 4,200 m under the Antarctic ice sheet, range in size from 1 km to 241 km long. The largest and deepest of these is Lake Vostok. This lake covers an area of 14,000 km² (about the same size as Lake Ontario, Canada), has a mean depth of 150 m, and a water residence time estimated to be around 50,000 years. Others are found in the Dome C and Ridge B regions of eastern Antarctica (Siebert et al., 2001). To date the subglacial lakes in Antarctica have remained unexplored except using remote technology. The intriguing question is what these subglacial lakes are likely to contain biologically, and what their accumulated sediments might reveal about the history of the ice sheet. In terms of life, the evidence to date suggests that scientists might discover communities of microorganisms, as the ice core extracted from above Lake Vostok has revealed a diversity of yeasts, Actinomycetes, algae, and spore-forming bacteria. Some of these organisms have remained viable in the ice for 36,000 years. Since the ice above Lake Vostok is over 500,000 years old, there is speculation that the lake will contain microbial genomes which have been isolated from the rest of the biological world for that period. The prospect of analyzing these subglacial communities, their genetics and physiology might open up a wide variety of questions concerning Antarctic biogeography and microbial evolution (Doran et al., 2004).

Physical, chemical, and biological features of the lakes

Physically, the lakes experience low temperatures (<10°C) and have varying degrees of ice cover usually between 1.5 and 6 m thick during winter. Some ice cover is permanent (perennial) while in other lakes increased summer temperatures can cause the ice to melt completely, or peripherally forming moats. The ice forms a thermal barrier that prevents most lakes from freezing to the bottom. Nevertheless, a minority of shallow lakes are not sufficiently protected from the wind and can freeze to the bottom such as Lake Ferris in the Larsemann Hills, or freeze to within a few centimeters of the bottom where the ice overlies a thin layer of hypersaline brine such as Lake Vida in the McMurdo Dry Valleys and Forlidas Pond in the Dufek Massif. These are known as dry-based lakes. Other lakes are ice-free or nearly ice-free all year round on account of hypersalinity, examples being Deep Lake in the Vestfold Hills, Don Juan Pond in the McMurdo Dry Valleys, and some lakes in the Rauer Islands. Ice and snow cover results in low levels of annual photosynthetically available radiation in the lakes. However, when the ice melts in summer, the high transparency of the water column can transmit so much light that it has an inhibiting effect on photosynthesis.

Chemically, the lakes range from some of the freshest lakes in the world to hypersaline lakes with concentrations of salt exceeding eight times that of seawater, preventing

them from freezing over, even during winter when their water column temperatures can drop below -10°C. Many saline lakes exhibit seasonal or permanent stratification of their water columns due to temperature and salinity gradients. Epishelf lakes such as Kakapon Bay in the Bunger Hills can exhibit full marine conditions together with a marine flora and fauna including seal populations. Others, like Moutonnée Lake on Alexander Island, have marine water restricted to the lower parts of the water column. Depending on the degree of chemical influence from the sea, versus interior climate regimes, lakes are often classified as “coastal maritime” or “coastal continental.” The nutrient status of Antarctic lakes is typically oligotrophic, with eutrophy usually restricted to those which are directly influenced by visiting marine mammals, birds, or people.

Biologically the lakes contain few zooplankton and no fish. Mosses are the highest forms of aquatic plant life on the continent, while higher plants and some emergent vegetation are present in lakes on the peri-antarctic and sub-Antarctic islands (e.g., South Georgia). Phytoplankton and bacterioplankton populations are present in most lakes and experience large seasonal variations in their populations, often related to the light climate. However, the bulk of the biomass and primary productivity is benthic, consisting of cyanobacteria, diatoms, and green algae, often in luxuriant mats several meters thick (Vincent, 2000; Ellis-Evans, 1996). The mats can be grazed by communities of rotifers, ciliates, and crustacea, though usually these zooplankton are present at low densities. Benthic microbial mats are less common in the saline lakes, but even the most saline ones contain some biota. Other biological habitats include pockets within the lake ice, the under surface of the lake ice, and the micro stratified chemoclines of meromictic lakes where gradients of conductivity, oxygen, pH, and sulfur provide numerous niches for photosynthetic sulfur bacteria, other anoxic bacteria, and methanogenic Archaea.

The biological communities of Antarctic lakes utilize truncated food chains characterized by the microbial loop (Laybourn-Parry, 1997) in which heterotrophic and phototrophic bacteria and small eukaryotic phytoplankton are consumed by heterotrophic nanoflagellates (HNAN), which are themselves consumed by larger protozoa and then metazoa, linking the energy lost as dissolved organic matter (DOM) back (loop) to zooplankton and other consumers of net plankton. DOM can enter the pelagic environment from a variety of sources: excretion of dissolved organic carbon (DOC) by algal cells, algal cell lysis by inefficient grazing by mesozooplankton, or diffusion from fecal pellets. The food web is therefore driven by recycled carbon.

Despite a biological composition that is primarily microbial, what the Antarctic lake biota lacks in size, is more than makes up for in biomass and species diversity; both considerably greater than that found in adjacent Antarctic terrestrial environments (Vincent, 2000). In fact, with many higher organisms unable to survive there, the

Antarctic continent could be seen as a microbial world with the lakes being its principal bastion. A recent study of the species composition of benthic microbial mats from selected lakes in the Larsemann Hills, Vestfold Hills, and McMurdo Dry Valleys found 1500 strains of bacteria (in a subset of 9 lakes), 60 strains of cyanobacteria (24 lakes), 230 strains of fungi (17 lakes), 91 strains of algae (3 lakes), and 50 protozoans (6 lakes). These were identified using combinations of morphology, phenotypic, chemotaxonomic, and molecular taxonomy. For bacteria, 320 clones were obtained from a single mat sample that would fit into a teaspoon! Technological advances have enabled scientists to study species compositions ranging from aerobes to anaerobes, from primary producers to degraders and brought a new level of detail to understanding of Antarctic lake food-web ecology.

The origin of the biota in Antarctic lakes

With this remarkable diversity of life present in Antarctic lakes, there has been an ongoing debate on its origins (see Gibson et al., 2006 for an authoritative account). The key question is whether the biota are primarily postglacial colonists, arriving through dispersal from sub-Antarctic islands and more northerly continents (e.g., South America) that had remained ice-free, or whether they are vicariant, surviving glacial advances in lacustrine refuges, and then recolonizing newly deglaciated areas. The latter model allows for a greater degree of endemism and the possibility that Antarctic lakes could contain species that are relicts of Gondwana.

Recent field data has provided the first hard evidence of zooplankton that have survived an entire glacial cycle. Thus, it is likely that non-glaciated lakes, epiglacial lakes, and cryoconite holes, for example, have provided refugia for many of the species found in Antarctic lakes, during past glacial cycles. There is also evidence of species that have become extinct in particular environments during glaciation and species that have dispersed to the Antarctic in the present interglacial from the maritime and sub-Antarctic islands and from the other higher latitude continents of the southern hemisphere (South America, Australasia). The different groups that comprise the vicariant species and the colonizers are usually differentiated by their life history, in particular the presence or absence of a life history stage capable of dispersal across the formidable barriers of the polar frontal zone and the circumpolar winds of the Southern Ocean.

Antarctic paleolimnology

Many Antarctic lakes accumulate sediment deposits that incorporate the products of glacial erosion together with biological and chemical fossils. These inorganic, biological, and chemical deposits respond rapidly to changes in temperature, precipitation, evaporation, light environment, ice cover, and glacial extent. Thus, lake sediments

can document both the lake's development and changes in the surrounding environment and have proved invaluable not only in determining the lakes' histories but also in addressing some major questions in Earth system science (Hodgson et al. 2004). For example, the onset of sedimentation in lake basins has provided data on the extent and timing of glaciation and deglaciation and environmental change. Lakes situated below the Holocene marine limit that have been isolated from the sea contain a record of the isolation event and this can be dated using radiocarbon technologies. From this it is possible to construct a history of marine transgressions and hence the relationship between relative sea-level change, ice thickness, global eustatic sea-level change, and isostatic rebound. Such data are enabling ice sheet modelers to accurately reconstruct the past, and better predict the future, contribution of Antarctic ice to global sea-level change. This is a pressing task as predicted increases in global temperature over the coming decades threaten the stability of some parts of the Antarctic ice sheet which, in total, has sufficient ice to raise global sea levels by as much as 70 m. Although this volume is highly unlikely to melt, evidence from the last interglacial, which was only very slightly warmer than our own (1–2°C), shows that global sea levels were 5 m higher than they are today and it is likely that high latitude ice reservoirs provided the source.

Epishelf lakes are also yielding valuable paleolimnological information on the ice shelves and glaciers that impound them. For example, sediments from Moutonnée Lake on Alexander Island have revealed that the currently extant George VI Ice Shelf broke up in the early Holocene, following a period of atmospheric warmth and at the same time as an intrusion of warm water under the shelf. The history of ice shelves is important as ice shelves help restrain the glaciers that flow into them, on account of being pinned to submerged rises in the ocean floor. Without the restraining ice shelves it is proposed that the inland ice of Antarctica could flow at an accelerated rate into the ocean and thereby increase the Antarctic contribution to global sea-level rise.

Paleolimnological studies have also tracked changes in lake salinity from which the atmospheric moisture budget can be inferred and compared with the evidence from Antarctic ice cores. Other studies have tracked the origin and development of the lake biota and, from this, made inferences about the nature and direction of environmental change.

Despite clear signs of marked recent environmental changes in the Antarctic we, as yet, have only a limited perspective on how Antarctic climates and environmental conditions have varied in the past. As long-term monitoring programs in high-latitude regions have only been established for the past several decades, paleolimnological methods will continue to have a role in developing our understanding past environmental changes and helping us to anticipate the magnitude, nature, and direction of future change.

Introduction

Subglacial Lake Ellsworth is located near the Ellsworth Mountains in West Antarctica at 78.9°S 90.6°W. The lake basin is in the center of the West Antarctic Ice Sheet (WAIS) in the Pine Island Glacier drainage basin, 20 km from the ice divide with the Institute Ice Stream. The lake is believed to be approximately 10 km long and over 3 km across at its widest point. The gradient of the bed surrounding Lake Ellsworth is at least twice as great as the lake surface, which implies that the depth of the lake could be of the order of tens if not hundreds of meters (Siebert et al., 2004). The ice overlying the lake is between 3.2 and 3.4 km thick, suggesting that the lake surface

is over 1 km beneath present sea level. Lake Ellsworth is located within a distinct topographic hollow, which is ~1.5 km deeper than the surrounding bed. The basin is fjord like in its topographic setting, and is one of a series of fjord-like over-deepening on the western flank of the Ellsworth Subglacial Highlands.

This summary of Lake Ellsworth will first document the series of radio-echo sounding (RES) transects from which the lake has been identified. Basal thermal regime and ice flow conditions which are believed to control the lake will then be described. The final section will describe future plans for the exploration of Lake Ellsworth (Lake Ellsworth Consortium, 2007).

Radio-echo sounding data

Subglacial lakes can be identified on RES records (see entry for “*Antarctic Subglacial Lakes*”). Two independent airborne and one ground-based RES campaigns have identified Lake Ellsworth:

1. The first knowledge of Lake Ellsworth is reported in Siebert et al. (2004), and is restricted to one RES line, acquired in 1977–1978 (Figure 1). Later RES profiles (described below) suggest that the sounding line is near parallel to the lake’s long axis, and is also near parallel to ice flow over the lake. This fortuitous occurrence is ideal for modeling the lake environments. The mean gradient of the lake surface reflector is 0.02, about ~11 times the ice surface slope, suggesting the lake is in hydrostatic equilibrium with the overriding ice. The slope of the ice base across Lake Ellsworth is not entirely constant; being concave over the lake’s upstream side and convex across its downstream side. In other words, the ice sheet “sags” as it flows onto the lake, and buckles against the sidewall as it regrounds. The same features have been identified over Lake Vostok and are an expected characteristic of deep-water subglacial lakes. In the cases of both lakes, the strength of the reflections from the ice–water interface varies near the shores, as a consequence of the reflector’s shape (Siebert et al., 2004).
2. In austral summer 2004–2005, the British Antarctic Survey flew a sounding line across Lake Ellsworth in the form of a bow, crossing the lake twice (Figure 1). Part of a 35,000 km grid pattern being collected over Pine Island Glacier also crossed the lake and identified other lake-like reflectors in the surrounding area. These lines were collected using 150 MHz ice-sounding radar (PASIN) (Vaughan et al., 2006). The new PASIN lines confirm the bright specular nature of the reflector and show a much shorter reflector than the 1977–1978 survey, of between 1.5 and 2.3 km in length. This suggests that the lake is long relative to its cross-profile, occupying a fjord-like basin on the flanks of the Ellsworth Subglacial Highlands.
3. In January 2006, a ground-based Chilean expedition traversed the Institute Ice Stream to Lake Ellsworth and acquired several RES transects over the lake.

Antarctic Subglacial Lake Ellsworth, Figure 1 (a) The location of Lake Ellsworth. The yellow box denotes bed information given in (c). Transect AB is provided in (b). (b) Raw 1977–1978 RES transect. The subglacial lake is located between 28 and 38 km. (c) Basal topography of the immediate area of Lake Ellsworth. (Adapted from Siegert et al. (2004).)

A 150 MHz RES system (CORDS) was used to collect nine lines totaling 15 km over the lake-like reflector (Rivera, personal communication 2006). These lines bound the lake to the north and west, though do not constrain its upstream margins to the south and east. Transitional zones are identified, showing a distinctly different radar response than that of the lake-like reflector or surrounding bedrock, possibly representing water-saturated sediments around the lake, thin water layers, or discontinuous water bodies.

Basal thermal conditions and ice flow modeling

The basal heat flux calculated in West Antarctica from temperature gradients in boreholes is around 70 mW m^{-2} (e.g., Hulbe and MacAyeal, 1999). Numerical thermodynamic evaluations suggest that the subglacial environment above Lake Ellsworth is warm, i.e., at the pressure melting point (Siegert et al., 2004). Due to increased ice thickness at the last glacial maximum (LGM), it is expected that the ice sheet was also warm based at the LGM. This indicates that Ellsworth may have existed during both the present interglacial and the LGM.

Ice flow modeling of the lake environment using internal layer architecture to invert for basal melting also suggests that the dominant process at the basal boundary condition is one of melting (Siegert et al., 2004). The model predicts that as ice flows over the lake, basal melting is expected at a rate comparable to the surface accumulation rate (which, near the ice divide, is $\sim 17 \text{ cm year}^{-1}$) (Siegert et al., 2004). This melt rate is significantly greater than that calculated for Lake Vostok, though is comparable to the situation in Lake Vostok in terms of its value as a proportion of the surface accumulation rate. As melting is the driving force behind water circulation (Mayer et al., 2003), the enhanced rates of melting predicted by the model may lead to circulation in Lake Ellsworth being stronger than Lake Vostok (and many other subglacial lakes). Upstream of Lake Ellsworth a small region of basal accretion is modeled at a rate of 20 cm year^{-1} . It is not yet known whether this freezing rate is real, or whether three-dimensional flow of ice (not accounted for in the model) complicates ice flow upstream of the lake and influences the internal layer structures. As the rate of water supplied to the lake is considerable, it is likely that Ellsworth is part of a wider subglacial hydrological network, feeding water into the basal environment of the Pine Island catchment.

Future research plans for Lake Ellsworth

A proposal to undertake a comprehensive geophysical survey of Lake Ellsworth, including ground-based RES, seismic surveying to calculate water depth in the lake and a variety of surface measurements, has been funded through the UK Natural Environment Research Council. The survey is planned in two seasons during the years of the International Polar Year (IPY) 2007–2009. Data collected during the IPY will supplement those acquired in 1978 and 2004–2006. As a consequence of these

geophysical results, Lake Ellsworth and its subglacial catchment will be characterized at a sub km resolution. It is a well-established hypothesis that Antarctic subglacial lakes house unique forms of life and hold detailed sedimentary records of past climate change. Testing this hypothesis requires in situ examination. Of the 145 subglacial lakes known in Antarctica, Lake Ellsworth stands out as a candidate for first exploration for the following reasons:

- The base of the West Antarctic Ice Sheet has been accessed, sampled, and measured. Accessing Ellsworth would, therefore, be less environmentally sensitive compared to accessing an East Antarctic subglacial lake.
- Lake Ellsworth is located close to the ice divide, so drilling from the ice surface into the lake will not be complicated by ice flow.
- Lake Ellsworth can be meaningfully characterized by geophysical methods.
- The sediments across the floor of Lake Ellsworth may contain a record of West Antarctic Ice Sheet history.
- The geological setting of the lake is better understood than any other Antarctic subglacial lake, as there is substantial outcrop of rock in the nearby Ellsworth Mountains.
- The ice sheet surface elevation over Lake Ellsworth is 2,000 m above sea level, more than a kilometer lower than the ice surface over East Antarctic subglacial lakes. Altitude-related problems encountered by scientists at the center of the East Antarctic Ice Sheet would not be an issue during the study of Lake Ellsworth.

A consortium of over 20 scientists from 7 countries and 14 institutions has been assembled to plan the exploration of Lake Ellsworth. Lake Ellsworth will be accessed using clean technology hot water drilling. Once lake access is achieved, a sterile probe will be lowered down the borehole and into the lake. The probe will contain a series of instruments to measure the lake water and sediments and will be tethered to the ice surface through which power, communication, and data will transmit. The probe will be dropped down the water column to the lake floor. The probe will then be pulled up and out of the lake, measuring its environment continually as this is done. Once at the ice surface, any samples collected will be taken from the probe for laboratory analysis. The duration of the science mission, from deployment of the probe to its retrieval, is likely to be between 24 and 36 h. Measurements to be taken by the probe include depth, pressure, conductivity, temperature, pH levels, biomolecules (using life marker chips), anions (using a chemical analyzer), nitrogen isotopes (using a tuned laserdiode), visualization of the environment (using cameras and light sources), dissolved gases (using chromatography), and morphology of the lake floor and sediment structures (using sonar). After the probe has been retrieved, a sediment corer may be dropped into the lake to recover material from the lake floor. Given that the comprehensive geophysical survey

of the lake will take place in two seasons during 2007–2009, a 2-year instrument and logistic development phase from 2008 (after the lake's bathymetry has been assessed) makes it possible that the exploration of Lake Ellsworth could take place in 2010–2012.

Introduction

Of the 145 subglacial lakes identified in Antarctica, the largest is Lake Vostok, the seventh largest lake on Earth (Studinger et al., 2004). Lake Vostok is situated in central East Antarctica at approximately 77°S and 106°E, between the Gamburtsev subglacial mountains and the

Aurora Subglacial Basin. A dense grid of radio-echo sounding (RES) records show that Lake Vostok is up to 260 km long and 80 km wide and the surface area is ~14,000 km² (Studinger et al., 2003). Local subglacial topography is very rugged to the west of the lake (ranging from –300 m to +2,400 m asl between the lake and 90°E), in contrast to smoother surfaces to the east (Studinger et al., 2003). A ~11 km wide and 30 km long embayment, separated from the main lake by a narrow bedrock ridge at the south-western shore, has also been identified (Studinger et al., 2003). The most recent geophysical surveys of the lake (consisting of laser altimeter, ice-penetrating radar, and gravity measurements) have shown that it consists of two sub-basins, separated by a ridge with very shallow water depths (Studinger et al., 2004). The southern basin is much deeper and approximately twice the spatial area of the smaller sub-basin to the north. Estimates of water depth from seismic investigations, RES-derived information about the bedrock slopes at the lake's margins, and aerogravity measurements, are several hundred meters and reach a maximum of 0.5–1 km near Vostok Station (Siegert and Ridley, 1998; Marsolov et al., 2001). The best estimate of the water volume based on aerogravity data is 5,400 ± 1,600 km³ (Studinger et al., 2004). The average ice thickness above the lake varies from ~4,300 m in the north to ~3,700 m in the south (Studinger et al., 2003), creating pressures in the lake in excess of 350 atm. The ice–water interface slopes downward from south to north with a gradient of ~0.002, which is 11 times that of the ice sheet surface, but in the opposite direction, implying the ice is in hydrostatic equilibrium with the underlying lake (Oswald and Robin, 1973).

Tectonic controls and lake history

The lake occupies a very large topographic depression, with a crescentic shape, similar to a rift valley. Lake Vostok may therefore occupy a rift valley formed by extensional tectonics, or may be a feature eroded by the ice sheet (Studinger et al., 2003) but most likely is a product of the two processes. There is presently no basis for estimating when the Vostok basin developed, but if it is linked in age with the Gamburtsev mountains nearby, this would be at least 30, and more likely >50, million years ago (Barrett, 1999). A liquid water lake formed in this depression when the ice became sufficiently thick to reach the pressure melting point (–3°C). The youngest possible age of lake water is the same as the ice at the base of the ice sheet, 420,000–1,000,000 years old. Some of the water could be as old as Lake Vostok itself if the lake is stratified (Siegert et al., 2003). It is thought that a subglacial lake could have existed in this location for as long as the ice sheet has been at a continental scale, which may be at least 15 million years (Summerfield et al., 1999). Sediments on the lake bed could be significantly older than the water if a subaerial lake existed prior to glaciation, provided that the advancing ice sheet did not scour them out of the basin.

Ice motion, subglacial melting, and freezing above Lake Vostok

Ice flow above Lake Vostok is NNW to SSE in the northern part of the lake, and W to E in the southern part (Tikku et al., 2004). Ice velocity measured using GPS and repeat-pass synthetic aperture radar interferometry (InSAR) from the ERS-1 satellite ranges from $3.0 \pm 0.8 \text{ m a}^{-1}$ to 4.2 m a^{-1} at Vostok Station (Bell et al., 2002; Kwok et al., 2000), such that ice would take approximately 15,000–20,000 years to cross the lake. The liquid water in Lake Vostok results from melting of the ice sheet in the north where the ice is sufficiently thick to reach the pressure melting point. Melting here is thought to be approximately balanced by lake refreezing to the underside of the ice sheet in the south, where the lake water is colder than the pressure melting point, so that the volume of water in the cavity does not change. Melt and freeze rates vary from a few millimeters to a few centimeters per year (Siegert et al., 2001; Bell et al., 2002).

Residence time and water circulation

Estimates of the residence time of water in the lake vary from ~40,000 to 300,000 years (after Bell et al., 2002 and Siegert et al., 2001). Circulation of water in the lake can only be predicted from theoretical models until the lake is accessed directly. Two possible scenarios have been modeled:

1. If the lake water is fresh, melt water formed in the northern region will be colder and denser than the resident lake water so will sink to the lake floor. Background geothermal heat will raise the temperature of this water above that of the overlying layers, decreasing the density and producing plumes of water that rise to the ice–water interface before cooling and sinking again.
2. If the lake water is saline, the fresh glacial meltwater will be buoyant compared with the resident lake water. The meltwater from the north would probably move southward and upward along the ice–water interface and eventually enter a region where it is below the melting point and refreeze onto the ice sheet.

Any circulation patterns are likely to be complicated by the Coriolis force and the complex geometry of the basins, which might introduce horizontal transfer and, to a lesser extent, vertical overturning (Siegert et al., 2003). However, there will always be an overall transfer of water from the north to the south (Siegert et al., 2001).

The chemical and biological composition of Lake Vostok

The composition of water in Lake Vostok has been inferred from ice retrieved from the bottom of a deep ice core above the southeastern corner of the lake. The so-called Vostok ice core has been drilled down to 3,650 m, stopping about 100 m above the lake's surface

in 2005. The top 3,538 m of the core is glacier ice and provides a detailed paleoclimate record spanning the past 420,000 years (Petit et al., 1999). The ice between 3,539 and 3,650 m has very different characteristics to the overlying glacial ice. The crystal size increases dramatically from a few cm to $<1 \text{ m}$, electrical conductivity decreases to the detection limit and numerous sediment particles are visible (Souchez et al., 2000). This ice has been interpreted as accretion ice, i.e., lake water frozen to the underside of the ice sheet. As this ice provides a sample of the lake water, it has been used to estimate the lake chemistry and biology.

Chemical composition

Soluble and insoluble impurities are added to the lake from the melting glacial ice and from the physical and chemical weathering of rock in the lake. The melting ice contains a very dilute mix of marine-derived aerosol, calcium-rich dust, and strong acids (e.g., nitric and sulfuric acid) (Siegert et al., 2003). Solutes are almost completely excluded from the ice crystals as freezing takes place, such that they are expected to build up in the lake over time until the inputs and outputs of solutes become balanced. However, the predicted salinity of the lake water from chemical analysis of the accretion ice is still very low and it would be classified as a relatively soft water lake (Wetzel, 2001). The idea of a very fresh water body agrees with the level of attenuation of radio waves in the water column that has been measured (Gorman and Siegert, 1999). The composition of the water is believed to be similar to runoff from other glacial environments, which is often characterized by rock–water interactions.

Sediments are introduced to Lake Vostok from the melting basal ice and the production of subglacial “rock flour.” Much of this material will remain suspended in the lake causing the water to be very turbid. Larger sediments will settle through the water column before accumulating on the lake bed. Although the melt rate is in the order of millimeters per year, sediments may have been building up gradually for millions of years, producing a layer tens to hundreds of meters thick. Sediments deposited across the floor of the basin before glaciation may not have been completely scoured by the advancing ice sheet, as a historical record from the mid-Cenozoic is present in the deepest sediments (Siegert et al., 2003).

Estimating the gas concentration in Lake Vostok is complicated by the existence of gas hydrates (gases trapped in cages of water molecules). Hydrates may partly or fully dissolve in the water, depending on the concentration of gases already present in the lake, but will remain stable after the dissolved gas concentration reaches a critical point, effectively buffering gas concentrations against short-term variations in source and sinks. Air will reach saturation in a minimum of 0.16–1.6 Ma (assuming contemporary melt and freeze rates) if there are no sinks within the lake and no significant transfers of water between other subglacial lakes. Therefore it is possible that the lake is already saturated with gas from the ice

sheet. The total dissolved gas in equilibrium with hydrates was estimated to be 2.5 l per kg of water (at 273 K and 1 atm) (McKay et al., 2003). Some gases may be utilized by chemical reactions (e.g., oxidation of reduced compounds) and biological processes. The consumption of gas by these processes may cause certain regions in the lake to become suboxic or anoxic, especially if the lake is stratified. For example, the oxidation of organic carbon in the sediments on the lake bed may deplete dissolved O₂ which cannot be replaced because of poor diffusion of gas in the sediments. The estimates of gas concentrations may need significant downward revision if Lake Vostok is found to be part of a connected hydrological system because gases will be able to leave the lake.

Biological composition

Microbial life is known to have developed biochemical, physiological, and morphological diversity to enable survival and growth in extreme temperatures, pressures, salinities, and pH values in environments containing liquid water (Rothschild and Mancinelli, 2001). It would therefore be surprising if some form of life was not present in Lake Vostok. Because the lake is permanently dark, organisms must either obtain their energy from organic matter in the lake (heterotrophic reactions) or make their own from chemical sources (chemoautotrophic reactions). The predicted dissolved organic carbon in the lake (<1,200 µg l⁻¹) is low, but adequate to support heterotrophic growth (Priscu et al., 1999). Total nitrogen concentrations in the accretion ice are sufficient to sustain ~10⁶ cells ml⁻¹ (Priscu et al., 1999). The life-supporting nutrients and gases, and hence any life, may be concentrated near the melting ice–water interface where they are introduced to the lake, or on the bed in the presence of nutrient-rich sediments.

Four independent laboratories have found very low counts and low diversity of bacteria in the accretion ice above Lake Vostok (Priscu et al., 1999; Karl et al., 1999; Christner et al., 2001; Abyzov et al., 2001; Bulat et al., 2004). Based on the cell concentrations in the ice and partitioning coefficients for the water to ice phase change, it is estimated that Lake Vostok contains 10⁵–10⁶ bacterial cells per ml (Christner et al., 2006). Metabolic and culturing experiments have demonstrated that a portion of the assemblage in the accretion ice is metabolically active when exposed to liquid water and nutrients (Karl et al., 1999; Christner et al., 2001).

Molecular identification of microbes within the accretion ice (by culturing and small subunit rRNA gene amplification) show close agreement with present-day surface microbiota, consisting of phylotypes within bacterial divisions Proteobacteria (alpha, beta, gamma, delta), Low G + C Gram positives, Actinobacteria, and the *Cytophaga-Flavobacterium-Bacteroides* line of descent (Priscu et al., 1999; Christner et al., 2001; Bulat et al., 2004; Christner et al. 2006). This may suggest that the bacteria in Lake Vostok do not represent an evolutionary

distinct community. The likelihood of a unique evolution in Lake Vostok depends on the timescale of isolation (how long microbes stay in the lake before being removed in the accretion ice) and whether the rate of evolution was sufficient to cope with the very high selective pressures in the lake. If Lake Vostok has survived since the onset of glaciation, the timescale of evolution could be as long as 15 Ma. This is not long enough for species-level divergence, but rapid genetic change may occur via recombination and mutator genes (Siebert et al., 2003). If microbes in the lake originated from basal sediments, they could be considerably older, such that they have been isolated long enough for evolutionary divergence. Unfortunately, the accretion ice only collects water from the surface of the lake and, therefore, may not capture ancient microbes that reside in deeper waters or on the bed.

Future exploration of Lake Vostok

In situ exploration of Lake Vostok is unlikely in the near future. Its colossal proportions and potentially distinct north and south basins make it very difficult to characterize in a meaningful way and make it unrepresentative of other subglacial lakes. Concerns over the potential contamination of the pristine environment will also have to be addressed. Further information about the planned exploration of subglacial lakes can be found in the entries for *Antarctic Subglacial Lakes* and *Subglacial Lake Ellsworth*.

Definition

Subglacial lakes are large pockets of water that lie beneath large ice sheets. Despite mean annual ice surface temperatures of below -50°C , background levels of geothermal heating ($\sim 50 \text{ mW m}^{-2}$) ensure that, where the ice is in excess of 3 km thick, basal temperatures can reach the pressure melting point. Subglacial water flows under the influence of gravity and ice overburden pressure. It can flow “uphill” if the magnitude of the ice surface slope is greater than 1/10th of the bedrock slope. Water collects, however, where basal slopes are larger, to form subglacial lakes.

Speculation about the existence of subsurface water in Antarctica took place in the 1950s and 1960s. The first reference to “lakes” in Antarctica was by a Russian pilot (R.V. Robinson) who identified features on the ice surface that resembled oval shorelines. The first evidence of subglacial lakes was derived from a technique called radio-echo sounding (RES), which utilizes VHF radio waves to measure the thickness of ice sheets in a manner analogous to seismic sounding. The technique was developed in the 1960s to comprehend the shape and volume of the Antarctic ice sheet. In the late 1960s and throughout the 1970s, RES was flown on long-range aircraft across approximately half of the Antarctic continent (and is still by far the largest of such surveys undertaken).

Subglacial lakes can be distinguished through three features of the reflected signal. First, the reflections are at least an order of magnitude stronger than from ice–rock contacts. Second, reflections are of constant strength across the lake, rather than the more common variable strength returns. Third, the surface of a subglacial lake is smooth and flat compared with the rough surrounding

Antarctic Subglacial Lakes, Figure 1 The location of 145 Antarctic subglacial lakes, shown as triangles with the exception of Lake Vostok, which is outlined. Colors refer to the surveys from which individual lakes were identified. (Adapted from Siegert et al. (2005).)

topography. Using these criteria enables the identification of subglacial lakes and, where more than one RES transect is available, their surface extents to be measured.

There have been three inventories of Antarctic subglacial lakes. The first listed the locations of 17 subglacial lakes (Oswald and Robin, 1973), the second provided details of 77 lakes (Siegert et al., 1996), and the third recorded 145 (Siegert et al., 2005) (Figure 1).

There are bound to be many more lakes, and so the final tally could be several hundreds. These inventories have revealed the size and distribution of Antarctic subglacial lakes including *Lake Vostok*, the largest and best known subglacial lake.

Recent research has discovered that, if subglacial lakes are fed with water, the pressuring effect results in sudden discharges, which may travel several 100 km, connecting several lakes together (Wingham et al., 2006). These

findings have changed opinions on whether subglacial lakes are isolated from each other, suggesting the lakes are interconnected in a hierarchical system of hydrological and therefore chemical and biological interchange.

Unless a lake is less than ~10 m deep, and its water is pure, the depth of water within a lake cannot be measured using RES because of the absorption of radio waves. Instead, seismic sounding must be used. Only three subglacial lakes have been measured using seismic sounding, however (*Lake Vostok*, in the south of the lake where the water depth is of the order of 0.5–1 km; *Lake Ellsworth*, where the water depth is ~150 m; and *South Pole Lake*, where the water depth is ~30 m). Hence, the volume of water held both within individual subglacial lakes, and in total beneath the Antarctic ice sheet, can only be estimated. If one assumes average water depths of between 50 and 250 m, the likely volume of water held in

subglacial lakes is around 6,000–22,000 km³ (equivalent to 15–70 mm of global sea level rise).

Subglacial lakes are not all the same. They can be characterized into at least three distinct groups: (1) those occupying entire subglacial hollows (including Lake Vostok); (2) those in relatively subdued topography, occupying only a small part of a larger subglacial trough; and (3) lakes that are “perched” across the stoss face of large subglacial obstacles.

Despite subglacial lakes being known about by glaciologists since the early 1970s, it took a seminal paper by Kapitsa et al. (1996), in which Lake Vostok was shown to be >500 m deep, to alert biologists to the possibilities of subglacial lakes as habitats for microbial life. If microbes exist in subglacial lakes, they must do so in permanent darkness and use chemicals, derived from ice melting into the lake and the rock and sediment beneath, to power biological processes. Subglacial lakes are therefore seen as analogous to extraterrestrial environments, such as the subsurface ocean of Europa. Furthermore, given that the East Antarctic Ice Sheet may have been in existence for up to 15 Ma, microbes in some lakes may have adapted in unusual ways to the extreme conditions encountered at the base of the ice sheet. Finding out whether microbial life exists in subglacial lakes is a driving goal of subglacial lake exploration, which has been in a planning phase for over a decade.

There have been six international meetings on Antarctic subglacial lakes (Cambridge 1994, St. Petersburg 1997, Washington DC 1998, Cambridge, 1999, Grenoble, 2006, Baltimore 2010). On each occasion, ways in which subglacial lakes can be explored have been discussed. It is particularly important to stress, given their pristine nature, that contamination of subglacial lakes must be avoided by exploratory programs. There are three ways in which a subglacial lake might be accessed: ice cores, thermo-probes, and hot water drills. While ice coring has been used to reach the bed of large ice masses on many occasions, it requires an antifreeze lubricant, which would be a major contaminant if it ever entered a lake system. Thermo-probes are devices that melt themselves downward into the ice, unwinding a tether to the surface as they do so. The advantage is that minimal contamination can be assured. The disadvantages are that much of the payload within the probe is taken up with the tether, restricting the science that can be done when in the lake, and the fact that the tether cannot be returned to the surface, which means that sample return is not possible. Tests on proto-type devices have been relatively unsuccessful, with problems of depth penetration and direction being caused by the sedimentary impurities within glacial ice. Hot water drilling, using a high-pressure hose to melt a hole in the ice, is a proven technique to access the beds of medium-sized ice sheets. It is gaining credibility as a means of exploring the base of large ice sheets. The advantage is that contamination can be restricted to melted ice (which is what lakes are made of). The disadvantage is that once melted, the borehole will refreeze,

limiting the period for an exploration experiment to little more than a single day. Several candidates for exploration have emerged in the last few years. One, named *Lake Ellsworth*, is worth noting as it is in West Antarctica. Here, the ice is much warmer and the location more accessible than for most lakes in East Antarctica, which makes exploration using hot water drilling feasible.

A second goal for subglacial lake exploration concerns the sediments that will accumulate on their floors. Glacial history of both the East and West Antarctic ice sheets is poorly understood, yet is critical to evaluating past global changes. For example, it is not known whether the East Antarctic ice sheet has remained in a stable form or not over the past 15 Ma. Moreover, despite acknowledging that the West Antarctic Ice Sheet is at risk of collapse, scientists currently have little idea as to when it last disappeared. Such information may be held within sedimentary material on the floors of subglacial lakes.

AQUATIC PLANTS

Stewart J. Clarke
 Natural England, Peterborough, UK

Introduction

Aquatic plants, frequently referred to as *macrophytes* or *hydrophytes* are an important functional component of many lakes and reservoirs (see, for example, Carpenter and Lodge, 1986). These terms are commonly applied to the vascular plants, mosses, and larger forms of algae (in particular filamentous algae and the stoneworts – Characeae) which are visible to the naked eye; smaller algae and phytoplankton are excluded. The vascular aquatic plants have not evolved in water but have descended from terrestrial plants. As such they show strong physiological similarities to their terrestrial

ancestors but exhibit some adaptation to submerged and waterlogged conditions (Sculthorpe, 1967). Most standing water bodies support some macrophytes and where they occur these plants are an important source of habitat and food for other organisms and have a key role in nutrient cycles and gaseous exchange through photosynthesis.

Growth forms

Plants growing in water exhibit a variety of growth forms related to the physical conditions in which they are growing and there is a clear link between life form and water depth. Aquatic plants are typically been divided into four categories – *emergent*, *submerged*, *floating leaved* and *free-floating* (Sculthorpe, 1967). However, these distinctions are arbitrary and some species exhibit different growth forms according to environmental conditions (environmental plasticity). Many species display different leaf forms depending on whether they are submerged or emergent. This *heterophylly* usually results in ovate, elliptic, or rounded emergent leaves and thin strap-like submerged leaves. The hydrology and morphology of the lake basin have a strong influence on both the presence and distribution of these different forms with emergents dominating in the shallower water areas and submerged species extending into deeper water (e.g., Pearsall, 1920).

Shallow water and periodically inundated areas on lake shores are characterized by *emergent* plants which grow rooted in substrate but have aerial photosynthetic parts (above the water surface). Emergent plants may grow in conditions that vary from waterlogged soils where water levels are up to 0.5 m below the surface to open water of 2 m depth. Although there are many dicotyledons with emergent growth forms, monocotyledons from the Poaceae (grasses), Cyperaceae (sedges), Juncaceae (rushes), and Typhaceae (reedmaces) tend to dominate in these conditions and can form extensive monospecific stands. These species commonly have large and extensive root systems and often spread through rhizomes. Emergent plants are a common feature of the *hydrosere* between open water and more terrestrial habitats and in lakes with shallow shorelines the emergent zone may be very extensive and part of a clear transition from terrestrial vegetation through to submerged flora. Such hydroseres are characteristic of semi-natural situations and are of high biodiversity value supporting a wide range of invertebrates and birds.

Submerged plants are those which grow with all photosynthetic parts beneath the water surface although in many species flowering parts may be held above the water surface to enable wind or insect pollination. Good examples are the exclusively aquatic plant families such as the Potamogetonaceae (pondweeds) and the Haloragaceae (water milfoils). Most submerged plants are rooted but compared to terrestrial and emergent species have reduced root systems. Other adaptations to submerged growth include limited woody tissue, thin cuticles, and large internal air spaces reflecting the additional support offered by

the surrounding water. Many submerged plants have finely dissected leaves which probably increase nutrient and light capture through their increased surface area (Wetzel, 1983).

Rooted plants with leaves that float on the surface of the water tend to have leaves with entire margins and thick waxy cuticles to minimize wave damage and water loss. Some species display heterophylly with both floating and submerged leaves of different forms. The ubiquitous water lilies (Nymphaeaceae) are the most well-known example of this life form. The *floating-leaved* growth form is generally restricted to water depths that allow leaves to reach the surface; in practice this is usually less than 2 m. However, some of the species in the group are able to grow in deeper water as submerged forms.

There is a further group of plants that are *free-floating* having no attachment to the substrate. These plants may be submerged such as the hornworts (Ceratophyllaceae) or more commonly surface floating such as the duckweeds (Lemnaceae). Free-floating plants generally spread through vegetative means, and as surface floating species are seldom light limited, they may spread rapidly. This propensity to spread and cover the water surface has the result that they may be invasive. Many of the invasive aquatic plant species which have caused economic or biodiversity problems have a free-floating growth form, for example, water hyacinth *Eichornia crassipes*.

Controlling factors

The distribution of macrophytes in lakes is determined by a range of factors but key determinants are light availability and wave exposure (see early work by Pearsall, 1920; Spence, 1967). Thus, macrophytes are generally confined to areas where light penetration is sufficient for photosynthesis and physical conditions allow relatively fine sediments to accumulate. Plant colonization depth is limited by light attenuation through the water column which is a function of water color and turbidity.

There is a relationship between light attenuation and depth of plant colonization. Macrophytes are restricted to the euphotic zone where net photosynthesis is possible; in practice for vascular plants this is the depth at which 1–5% of surface light remains (Wetzel, 1988). Where water transparency is very high it may be possible for Characeae or plants with an isoetid (low growing, rosette) growth form (e.g., Isoetaceae) to extend to more than 30 m. The ability of the Characeae to extend to greater depths may also be a function of pressure which may restrict vascular plants from the deeper areas (Spence, 1982). Some species particularly the stoneworts and some of the isoetid growth forms may form dense monospecific lawns at depth. Such growths are characteristic of particular lake types, for example, low-alkalinity oligotrophic lakes are characterized by isoetid species with different species commonly inhabiting different depths.

Clearly the amount of light energy reaching the leaf surface plays an important role in determining photosynthetic activity. Macrophytes compete with both phytoplankton and epiphytic algae (which use the plants as substrate) for light and nutrients (Phillips et al., 1978). This competition is a major factor in regulating the function of shallow lakes.

A major constraint to plant life underwater is the availability of carbon dioxide (CO_2). The diffusion of CO_2 in water is several orders of magnitude slower than in air and hence inorganic carbon availability may become a limiting factor for submerged plants. Some submerged plants have adapted to this through compensatory mechanisms using bicarbonate ions (HCO_3^-) as a source of carbon where free CO_2 is limited (Lucas, 1983) or aquatic acid metabolism (Cockburn, 1985). Plant nutrients such as phosphorus, nitrogen, and carbon may be important in determining the competitive relationship between macrophytes and algae but also on the actual species composition of macrophytes. There are well-established relationships between macrophyte communities and lake trophic status and documented species shifts with anthropogenic nutrient enrichment (Harper, 1992).

An important factor determining where plants occur within a lake basin is exposure to wave action. Exposed shores are unfavorable for plant growth as physical conditions prevent the buildup of fine nutrient rich sediments required for plant rooting and wave action physically damages plants. As a result in large basins plants tend to be concentrated in sheltered bays and areas of shoreline. Water level and the hydrological regime are also important in structuring emergent and submerged plant communities (Coops and Hosper, 2002). Groups of plants display different tolerances to water level and hence may be restricted to different areas of the shoreline and littoral zone. While plant communities may be adapted to seasonal fluctuations, fluctuations with much shorter return periods, often as a result of anthropogenic activities (e.g., hydropower schemes) are generally damaging, causing physiological stress to plants and leading to erosion (Hellsten and Riihimäki, 1996). For these reasons water supply reservoirs whether artificial or natural may have limited macrophyte communities.

Substrate is both an important source of nutrients and a means of anchoring for those plants which are rooted. There is an inter-relationship between sediment particle size and nutrient content. In general nutrient concentrations in sediments are orders of magnitude higher than in the water column and both emergent and submerged plants are known to obtain most of their nutrients from the substrate in spite of being able to source both phosphorus and nitrogen from the water column (Barko et al., 1991). Evidence suggests that sites of nitrogen and phosphorus absorption depend on a variety of factors including plant morphology (therefore species and phenotypes may differ in response); relative

concentrations in water and sediment; presence and type of organic matter; water column pH; and sediment density (see Denny, 1980).

The distribution of plants both within and between lake basins is also influenced by the modes of reproduction. Emergent species share many of the reproductive strategies of terrestrial plants and may be wind, water, or animal pollinated. Submerged species seem to be capable of sexual reproduction through seed but asexual reproduction through vegetative means prevails (Hutchinson, 1975). Aquatic species possess a range of different vegetative structures that enable them to reproduce modified stems such as stolons, runners, and rhizomes; modified buds such as turions; and specialized roots. As such long-range dispersal is highly dependent on water movements or animal vectors.

There is an affinity between certain macrophyte species or communities and particular lake types and as a result there have been a number of attempts to classify lakes according to their aquatic flora (Palmer et al., 1992). The visible nature of aquatic plant communities and these relationships between species composition and lake physical and chemical characteristics has led to aquatic plants featuring prominently in lake management and habitat conservation. However, this also reflects the important role that plants have in structuring communities of other organisms and controlling lake ecosystem function.

Functional role and importance

Where they occur plants may have a strong influence over in lake processes and overall ecosystem structure. Thus in shallow lakes where water depth allows plants to colonize large areas of the lake basin, overall lake function may be dominated by plants. Similarly the shallow littoral zone and sheltered bays of deeper lakes may be plant dominated. This influence is largely related to the effect of plants on nutrient dynamics and habitat structure.

Enrichment by phosphorus and nitrogen compounds leads to a range of undesirable impacts such as changes in macrophyte species composition at moderate levels of enrichment to the complete loss of submerged macrophytes and blooms of phytoplankton at high levels of enrichment (Harper, 1992). Macrophytes are in competition with phytoplankton for both light and nutrients. Under natural conditions where extensive macrophyte beds are present and external nutrient loads low, resultant concentrations of nutrients in the water column will also be low. Extensive beds of macrophytes act as a nutrient sink reducing phosphorus and nitrogen available for algae. Additionally, macrophytes stabilize sediments preventing resuspension of fine material and the associated nutrient flux to the water column and provide a refugia for zooplankton (e.g., large *Daphnia* spp.), invertebrates, and fish which graze on phytoplankton. Additionally the plants provide cover for large piscivorous fish (e.g., pike – *Esox*

lucius) which predate on smaller fish species that would otherwise suppress abundance and biomass of these phytoplankton grazers. Thus, macrophytes are important in mediating top-down controls on phytoplankton biomass.

These mechanisms are most pronounced in shallow lakes where plants can colonize extensive areas of the lake bed. It has been demonstrated that in these shallow lakes two alternative stable states can exist depending on the level of nutrient loading and the interaction of other factors (Scheffer et al., 1993; Scheffer, 1998). The macrophyte-dominated state as described is buffered by the effect of plants on other organisms and system. At high concentrations phytoplankton are able to shade out submerged plants leading to a loss of structure. This in turn reduces habitat for grazing zooplankton and predatory fish species. The number of small fish increases and in turn the size of zooplankton decreases, reducing grazing pressure. Thus, phytoplankton dominance reinforces the turbid water state. At intermediate nutrient concentrations either state is possible depending on other pressures. The introduction of bottom feeding fish, or the use of herbicides may reduce aquatic plant biomass acting as a “forward switch” toward a phytoplankton-dominated system. In management terms a “reverse switch” such as biomanipulation will be required to restore the lake to a plant-dominated state.

Although the interaction between macrophytes and phosphorus (and to a lesser extent nitrogen) has been the focus of much work and lake and reservoir management, macrophytes do influence other chemical and physical processes within lakes. For example, where there are abundant growths of submerged macrophytes high levels of photosynthetic activity can lead to short-term increases in pH and oxygen depletion. Equally submerged and emergent plant communities may be important in stabilizing accumulated fine sediments. Reduced exposure within stands may lead to sedimentation of particles and root structures may help improve the cohesiveness of substrate. The spread of littoral plant communities is a characteristic adjustment response where water levels have dropped and can have positive feedbacks by trapping more fine sediment and reducing water depth further.

As is evident from the alternative stable states model macrophyte stands provide important habitat complexity for other organisms. Emergent macrophytes of the littoral and shore zone are known to be important for fish recruitment providing a substrate for the eggs of some species and a refugia for fry. Birds also benefit from these stands of emergent vegetation and reedbeds are widely acknowledged to be important for many bird species. Macrophytes may also constitute an important food source as they may be a major source of primary productivity. A number of waterfowl species feed almost exclusively on submerged plants and many others may depend on fauna associated with these plants. Consequently deteriorations in water quality may affect associated bird communities as well as in lake flora and fauna.

Where they occur macrophytes are a vital component of standing water ecosystems exerting a strong influence upon ecological processes and trophic interactions. However, macrophytes are highly susceptible to the consequences of nutrient enrichment, a widespread pressure for standing waters. As a result macrophytes and the safeguard of these communities is often the focus of lake management especially where the concern is high-quality standing water ecosystems.

ARAB REGION, LAKES AND RESERVOIRS

Mamdouh Shahin (Deceased), Lars Bengtsson¹

¹Department of Water Resources Engineering, Lund University, Lund, Sweden

Brief description of the Arab region

Physical geography

The Arab Region is a land surface situated between 1°35'S and 37°N latitudes and between 60°E and 17°W longitudes. It covers an area of about 14 km² extending from northwest Africa in the west to the Gulf in the east. The region is bounded by a seacoast 20,000 km long, which results in an overall average ratio of 1.5 m coastline per km² land surface. The region is occupied by 22 states distributed between three subregions. The western subregion includes Mauritania, Morocco, Algeria, Tunisia, and Libya; the central comprises Egypt, the Sudan, Djibouti, Somalia, and Comoro Islands; and the eastern subregion comprises Syria, Lebanon, Jordan, Palestine, Iraq, Kuwait, Bahrain, Qatar, Saudi Arabia, the United Arab Emirates, Oman, and Yemen (Figure 1).

Dry, warm deserts cover the greater part of the surface of the region. The Great Sahara extends from eastern Mauritania to Morocco and Algeria, and further to southern Tunisia. The name changes to Libyan Desert in Libya

and Western Desert in Egypt. The Eastern and Nubian Deserts cover the areas east of the Nile Valley in Egypt and the Sudan to the western shore of the Red Sea. A number of deserts occupy most of the area between the Red Sea in the west and the Persian Gulf in the east including the Arabian Peninsula.

The region encompasses diversity of mountain ranges: the Atlas in Morocco and Algeria; Al-Hoggar and Tibesti in Libya; Al-Uweinat in Libya, Egypt, and the Sudan; Darfur and Kurdufan in the Sudan; the Zagros in Iraq; Taurus in Syria; Al-Hijaz and Asir in the Arabian Peninsula. The Omani Mountains lie in a tectonically unstable zone. Two parallel ranges in Syria confine between them the Ghab Valley. Coastal mountain chains run parallel to the shores of the Mediterranean Sea, the Red Sea, Gulf of Aden (Yemeni and Hadramaut Mountains), and Gulf of Oman. The peaks of these mountains vary from 1,500 to 4,000 m a.m.s.l. (above mean sea level).

Next to high plateaus and mountain ranges, the Arabian deserts include low-lying areas in the form of coastal plains, oases, and swamps occupying flat depressions, large and deep natural depressions, and lakes. Most of the lakes are in the interior, without connection to the sea. Exceptions can be found in northern Egypt where some lakes open to the sea can be found. Salty lakes (Chotts) can be found in certain countries like Algeria and Tunisia.

Arab Region, Lakes and Reservoirs, Figure 1 Map of the Arab Region and the perennial rivers and major wadis traversing its surface.

Geology

The geological history of the region goes back to the Precambrian period (more than 500×10^6 year BP), in which time the "African Shield" was formed. Crystalline rock has been exposed in large surfaces in Mauritania, Algeria, Libya, and Egypt and the Sudan. It is also exposed along the coast of the Red Sea and the Arabian Peninsula, forming that branch of the African Shield known as the "Arabian Shield." The split of the Arabian Shield, which took place in the period $135\text{--}65 \times 10^6$ year BP, indicates to the geological destruction or tectonic activity that led to the formation of a huge depression filled by the Red Sea. The volcanic activity in the same subregion, though relatively recent, has strongly affected the Horan Plateau, Al-DrUz Mountain in Syria, northern Jordan, and Saudi Arabia. More recent tectonic movements led to the formation of mountains and are responsible of the subsidence of the Arabian Shield in the Rub al-Khali Desert, Persian Gulf, Euphrates, and Damascus region.

During the Paleozoic and Mesozoic Eras, ($310\text{--}135 \times 10^6$ year BP), thick layers of sand and Nubian were deposited on the basement rock in northern Sudan and the Western Desert in Egypt and Libya. Thick layers of limestone were deposited later in the Mesozoic Era, 120×10^6 year BP in the Arabian Peninsula thereby increasing the material overlying the basement rock. Alternating series of lacustrine calcareous rock and sand were deposited during the Tertiary and Quaternary Eras in many areas in the region and formed Al-Hamada in Algeria and Morocco. The same deposits augmented by layers of limestone are present in Egypt, Syria, Iraq, and the southern part of the Arabian Peninsula. The Atlas region belongs to the Mediterranean region and is characterized by formations where clays, calcareous rocks, and dolomites of the Jurassic Period are dominant.

The unstable shelf of the Arabian Platform in the eastern subregion appears in the form of basins and swells in Syria, Jordan, and the Gulf States. The transition zone of the unstable to the stable shelf extends from Sinai to the Gulf of Aqaba and follows the Wadi Araba, Jordan. In Syria, it trends eastward and south eastward while in Saudi Arabia it trends southward and parallels the Persian Gulf. The Nubian-Arabian Shield occupies southern Sinai and the surroundings of the Gulf of Aqaba and Red Sea as far as the northern border of Yemen. Clastic sediments of continental rocks of the Precambrian basement complex characterize these areas.

Climate

The region is a transitional area between the equatorial and mid-latitude climates, with June–August as the warmest period of the year and December–February as the coolest period. Maximum day temperatures above 40°C occur for long periods in certain parts of Iraq, Saudi Arabia, Western Sahara, and the Egyptian-Sudanese borderlands. Summer temperature ranges between 30°C and 35°C in Syria, Iraq, Jordan, and Palestine, and gets higher on the coasts of the

Red Sea and Gulf of Aden. Contrarily, the temperature on the coasts of Libya, Tunisia, Algeria, Morocco, and on Al-Hoggar and Tibesti Mountains in Libya and the Yemeni Mountains is below 30°C . The summer night temperature in all said locations is at least 10°C lower than the respective maximum temperature. The minimum winter temperature is below 5°C in the northern Sahara and Libyan Desert, and below 0°C in the higher parts of the Atlas region. It rises at the Red Sea and the Arabian Sea coasts, and in the Rub al-Khali Desert to $10\text{--}15^\circ\text{C}$. In the southern tip of the Red Sea and the Gulf of Aden, it exceeds 20°C . The maximum day temperature in winter season is 20°C along the Mediterranean coast, 10°C or below in the Atlas region, below $10\text{--}12^\circ\text{C}$ in Syria, above 15°C in Mesopotamia, and $20\text{--}25^\circ\text{C}$ at the Red and Arabian Sea coasts (Martyn, 1992).

The eastern subregion is generally dry nonetheless well differentiated. The December relative humidity in Mesopotamia, the Gulf coast, the southern half of the Red Sea coast, and the Gulf of Aden is above 70%. In the same month, it is below 40% in the Rub al-Khali Desert and 30% in the Yemeni mountainous region. The relative humidity in June–August, driest season of the year, is above 65–70% along the Mediterranean and Red Sea coasts decreasing to 30% inland and 20% in Central Mesopotamia and Saudi Arabia. The monsoon causes the humidity to rise to 50–60% in the south of the Peninsula and around the Gulf of Oman and Persian Gulf. Over North Africa, it is low throughout the year. In the early morning hours of January, it falls from 80% to 90% along the coast to 40% inland. The July humidity can be between 5% and 20% in the Sahara causing the air to be dry to very dry.

Winter cloudiness in the Arabian Peninsula, except in mountainous areas, is 20–30% and rises to 45–60% in northern Syria and Iraq. Summer cloudiness in the Mediterranean region is 10–20%. The annual number of cloudless days is 300 at Aswan, Egypt, and over 100 in the Western Sahara including the Mediterranean coast. The Central and Eastern Sahara receive over $3,600 \text{ h year}^{-1}$ of sunshine increasing to more than 4,000 h in the Libyan, Nubian, and Arabian Deserts. Southward, the hours decrease as the rainy season becomes longer (2,900–3,000 h in southern Mauritania). Clouds blowing off the Atlantic also reduce the sunshine to 2,600–3,000 h on the coastal plain of Morocco, the High Atlas, and the coast of the West Sahara. Due to cloudiness mainly, the annual effective sunshine varies from 3,100 h in northern Iraq and on Lebanon mountainous to 3,300 h over Babel-Mandab Straits and in the interior of the Arabian Peninsula. The sunshine is least in January, ranging from 150 h in Lebanon, northwest Syria, and northern Iraq to 250 in southern Iraq and 300 h in southwest Saudi Arabia. The sunshine duration in July exceeds 400 h in the Syrian Desert and north Saudi Arabia, and 250 h in Yemen.

Those parts of the region in West Asia between 20° and 30°N receive annually above 200 kcal cm^{-2} extraterrestrial radiation. The January radiation increases from

4 kcal cm⁻² in Lebanon and western Syria to above 8 kcal cm⁻² along the line running from the Gulf of Aqaba to central Iraq, and further to 12 kcal cm⁻² in Bab el-Mandab Straits. In North Africa, the January radiation increases from 8 to 10 kcal cm⁻² in the north to 16 kcal cm⁻² in the south. The July radiation in the Syrian Desert can exceed 20 kcal cm⁻² while in the southern part of the Peninsula it falls to less than 18 kcal cm⁻². Martyn (1992) added that the solar radiation in the Sahara of North Africa is 200 kcal cm⁻² year⁻¹ increasing to 220 kcal cm⁻² year⁻¹ in the reach of the Nile Valley between Aswan, Egypt, and Abu Hamad, the Sudan, corresponding to 85–90% of the possible maximum extra-terrestrial radiation. The solar radiation is reversed in July bringing the energy to over 22 kcal cm⁻² in the Western Sahara along with the Libyan and Egyptian coasts. Westward the radiation energy reduces to 18–20 kcal cm⁻².

Aridity is a principal feature of the region. Precipitation, mainly in the form of rainfall, ranges from more than 1,000 mm year⁻¹ in certain parts of the Sudan, Lebanon, and Morocco to zero in desert areas. The available literature (e.g., Shahin, 1989) estimates the average annual rainfall in the region as 1.9×10^{12} m³ year⁻¹ or 140 mm year⁻¹.

Rivers and wadis

The mightiest river in the region is the Nile River system. It has been suggested that the Nile was made up of several subsystems each is related to a different geological time. The tectonic movements, which took place in the central subregion, have helped to establish hydraulic connection between the elements composing these subsystems. The Euphrates and Tigris Rivers, alike the River Nile, are international rivers. The Tigris supplies some of its water to Iraq while the Euphrates supplies some of its flow to Syria and Iraq. The River Senegal supplies Mauritania with its allocated share of water. This is not the case with the Shebelle and Juba Rivers, which flow naturally from Ethiopia to Somalia bringing whatever water left unused by the upstream countries. Wadi Zeroud (Tunisia), Cheliff (Algeria), and Sebou (Morocco) are national rivers. The principal feature of river flow in the region is its seasonality. The ratio of maximum to minimum flow is in the order of 10:1 (Figure 2a).

The surface of the region is intersected by a tremendous number of intermittently flowing watercourses (wadis) of different sizes, amounts of flow, and sediments. As the minimum flow is practically zero (Figure 2b), it is obvious that the seasonality of wadi flow can be considered as infinite. As the distribution pattern of the supply is different from that of the demand, water storage in reservoirs seems to be indispensable in many cases.

Lakes and reservoirs

Hydrology and water quality aspects

Before embarking on any presentations of lakes and reservoirs in the Arab Region, it might be worthwhile to start

Arab Region, Lakes and Reservoirs, Figure 2 (a) Long-term average hydrographs of the Nile River at four key stations. (b) Hydrograph of the Black Gorgol Wadi, Mauritania.

by a brief review of a host of items of general nature to lakes and reservoirs anywhere in the world.

Definition and classification of lakes and reservoirs

A lake is a relatively isolated stretch of water filling a depression mainly of natural origin. A lake system consists of a body of water and a basin. Lake basins, according to Smith (1998), are formed by certain activities such as: tectonic, volcanic, glacial, fluvial including shoreline processes, and wind action.

A reservoir is a natural facility where stream flow is stored in times of excess to be released in times of shortage. The contents of a reservoir, water and silt, begin to accumulate following dam construction. Flow regulation after a reservoir is put into operation serves one or more purpose(s) such as flood protection, irrigation, hydro-power development, navigation, domestic, and recreation. Reservoirs can be classified as small, medium, and large. Depending upon its operation, reservoir storage can be seasonal, annual, and over-a-year.

Effect on climate and environment

Lakes and reservoirs tend to modify the climates of the surrounding areas. Their effects vary with the areal extent and depth of water, configuration, characteristics of prevailing wind, and the general climatic environment within which the lake interacts. Large, deep lakes develop more substantial modifications than small, shallow lakes; the effects in areas of pronounced seasonal change are more significant than those in tropical areas. Eichenlaub (1998) attributed these effects to alterations of the boundary layer caused by thermal lag of lake surface temperatures and differences in moisture budget of lakes compared to temperature and moisture of the surrounding areas; alteration of winds by lakes due to changes in surface roughness; and to interactions of the three factors.

Thermal stratification is an important physical feature of a lake. The sun heats the water surface thus decreasing its density and resulting in the formation of a layer of less dense water (epilimnion) overlying a denser, cooler layer of water (hypolimnion). A transition layer (thermocline) separates these two layers. Shallow tropical lakes stratify and destratify more than twice a year while deep tropical lakes do not completely mix.

Major reservoirs have their environmental influences on the surrounding areas such as micro-climate change, leakage of water, induced earthquakes, and landslides. Water temperature changes, turbidity, eutrophication, and sedimentation do happen within the reservoir itself. Riverbed change, bank erosion, salt accumulation in river delta soils, deterioration of soil fertility, seawater intrusion, coastal erosion, and effects on wildlife and fishes are among the influences that might take place downstream the reservoir. Dam construction and reservoir storage also have their societal influences, for example, landscape preservation, forced displacement of population, protection of archeological relics, and development of water-borne and water-related diseases (Hori, 1991).

Eutrophication

Eutrophication can be defined as the enrichment of waters with plant nutrients, primarily phosphorus, and nitrogen leading to an accelerated plant growth (e.g., algae) above and beneath the water surface. When decaying, this plant material leads to depletion of the oxygen reserves of water bodies causing problems such as deterioration of water quality for drinking purposes, fish mortality, liberation of corrosive gases, and other undesirable substances which is a recreational and environmental impairment, and impairment of the holding capacity (OECD, 1982).

Depending on the amount of phosphorus, average water depth and mean water residence time, a reservoir or a lake can have eutrophic and oligotrophic zones separated by a mesotrophic zone. The ensuing eutrophication problems of natural lakes, estuaries, lagoons, and closed seas in North Africa have been described as identified while those of reservoirs, rivers, and irrigation systems are serious problems (Meybeck et al., 1989).

Morphometry

The important dimensions of the water body of a lake are the maximum and mean of each of the length, width, and depth. The effective length, relative depth, lake area, lake volume, volume development, and the relationship describing the change of surface area with depth are equally important. Hutchinson (1957) and later Kuusisto (1985) gave expressions combining these dimensions to establish the necessary parameters of the water body.

Mass balance of a lake

The balance of any system such as water, heat, salts, and sediments is an expression of equilibrium and is identical in all cases. The input part of the water balance of a lake consists of the direct precipitation and the inflow of surface and groundwater while the output consists of lake evaporation and the outflow of surface and groundwater. The sum of input items over a certain period of time added to the initial volume of water in storage reduced by the sum of outflow items over the same period gives the final volume of water in storage at the end of the chosen period. The difference between the initial and final volumes is equal to the change in storage.

Lake chemistry and mineralization

The chemical composition of lake water depends on the rock composition of the lake and its drainage basin, connection to the seawater, quality of runoff to the lake, and on the climatic zone. According to their mineralization (quantity of salts in solution), lakes can be grouped into freshwater (up to 1.0 g L^{-1}), brackish ($1.0\text{--}24.7 \text{ g L}^{-1}$), saline ($24.7\text{--}50 \text{ g L}^{-1}$), and hyper-saline (over 50 g L^{-1}).

Sedimentation

Saline and freshwater lakes have different deposits. The former may be predominantly evaporites interrupted by clastic sediments brought into the lake during sudden flooding. The sediments in freshwater lakes vary considerably in response to the nature of origin of the lake basin, character of the rock, and soil around the basin, characteristics of the drainage area, extent of shallow water near the shorelines, and the organisms dwelling in the lake. Recent deposits in most freshwater lakes are highly organic. Varves, which occur in lakes receiving or have received at some time in their history water from melting ice sheets, might be of interest to detect.

Reservoir sediments are mostly products of erosion processes taking place in the upper reaches of the catchment area. As the land slope decreases, the eroded material begins to settle in streambeds, flood plains, or in lakes and reservoirs. The sediments in this case are mostly of mineral origin. Part of the deposited sediments leaves the reservoir through dredging, by flushing, or is transported by the release to the downstream. The volume of sediments still left in a reservoir divided by the volume of sediments that entered it, both in a certain period of time, is called trap efficiency. This efficiency plays a major role in determining the life age of a reservoir.

Lakes in the Arab region

The region as described earlier includes a number of natural lakes and depressions. Some of these lakes are situated along the seashore and the rest are in the interior. Sixteen out of the twenty-two countries sharing the Arab Region do not have any natural lake of substance. These countries are: Morocco, Libya, the Sudan, Djibouti, Somalia, Comoros, Lebanon, Palestine, Jordan, Kuwait, Bahrain, Qatar, Saudi Arabia, United Arab Emirates, Oman, and Yemen. Lakes, chotts (saline, shallow lakes), and depressions that can be found in the remaining countries are given distributed on respective countries in Table 1.

The major characteristics, especially the water balance and quality of water, of some of the above-listed lakes and depressions are briefly reviewed in the next subsections.

Arab Region, Lakes and Reservoirs, Table 1 Major lakes in the Arab region distributed on countries

Mauritania	Lake Rkiz
Algeria	Cholt el-Hodna, Ch. ech-Chergui, and Ch. Melhrir
Tunis	Lake Meleh, L. Oubeira, L. Tonga, L. Benzert, L. Ichkeul, Chott Gueltar, Ch. Jerid, Ch. Fejaj, Ch. elGharsa, and Ch. el-Franji
Egypt	Lake Al-Zaranik, L. Bardawil, Great and little Bitter Lakes, L. Timsah, L. Manzalah, L. Burullus, L. Mariut, L. Edku, L. Qiirln, and Qattara Depression.
Syria	Lake Horns, L. Ateibe, L. el-Hijane, L. el-Ghuba, L. Khabrat Seiqal, and L. Khabrat Abu al-Husan.
Iraq	Lake Habbanyah, Bahr al-Milh, and Tharthar Depression.

Lake Burullus, Egypt. Al-Burullus Lake is a shallow, brackish lake situated along the Mediterranean coast and occupies a central position between the two branches of the Nile River in the Delta area (Figure 3). It is connected to the sea by a narrow outlet, 44 m in width. The lake is about 65 km long and 6–16 km wide. The present surface area of the lake is about 410 km² of which 370 km² is open water with a depth ranging between 0.42 and 2.07 m. The eastern part of the lake is the shallowest, with an average depth of 0.8 m. The lake volume at zero level is 328×10^6 m³. The lake bed overlies deposits of clay and sandy facies up to 1,000 m thick in the western part. Their absence in the eastern part may be related to erosion of an old branch of the Nile River. The catchment area of the lake is located between 30°22'00"–31°36'16"N latitudes and 30°29'00"–31°21'19"E longitudes. The elevation varies from about 20 m at the most southern edge to zero at the sea in the north with an average slope 0.00015.

The southern shore of the lake receives the agricultural drainage water of 74.3% of the Nile Delta region. The volume of water thus supplied is about 3.9×10^9 m³ year⁻¹. The discharge varies from 100 m³ s⁻¹ in February to 160 m³ s⁻¹ in July. Besides, the lake receives a mean annual rainfall (1912–1992) of 187 mm corresponding to 77.4×10^6 m³. Model studies have shown that the annual groundwater inflow to the lake can be estimated as 32.5×10^6 m³. As such, the total inflow to the lake is about 4×10^9 m³ year⁻¹. The lake evaporation has been estimated as 647×10^6 m³ and the seepage flow to the sea has been estimated from the difference in head between the lake and the sea, the hydraulic resistance of the top layer and the transmissivity of the deposits

Arab Region, Lakes and Reservoirs, Figure 3 Location map of some of the lakes and natural depressions in Egypt.

underlying the lake. The balance of inflow–outflow components using the flood routing technique yields an outflow to the sea of $3.2 \times 10^9 \text{ m}^3 \text{ year}^{-1}$. It is worthwhile to report that the tide estimated as the difference between the mean high water (0.33 m) and the mean low water (0.18 m) is small and its effect can be neglected.

Recent analysis of the drainage water has shown that the concentration of BOD ranges between 34 and 64 mg L^{-1} and of COD between 56 and 91 mg L^{-1} . The concentrations of heavy metals are rather low; 0.473–0.914 for iron, 0.002–0.476 for zinc and 0.013–0.184 for copper, all in mg L^{-1} . Biological activity, especially at certain sections of the lake is high. This has been attributed to the intensive application of nitrate and phosphorus fertilizers to the agricultural lands served by the drainage system. The Drainage Research Institute of Egypt (2004) observed that certain species of fishes and migrating birds are disappearing, there are marked changes in the chemical and bacteriological properties of lake water and indications to health impairment among some of the fishermen.

Lake Mariût (Mareotis), Egypt. This is one of the smallest natural lakes in Egypt. It is isolated from the Mediterranean Sea, extending some 10 km along the coastal strip of the sea west of Alexandria and 30 km to the south (Figure 3). The area of the lake was estimated in 1950 as 168 km^2 at elevation 3.0 m b.m.s.l., 714 km^2 at zero m.s.l. and 840 km^2 at elevation 1.0 m.a.m.s.l (Shafei, 1952). The figures given by the Water Researches Center, Egypt, lately show that the gradual drying up of certain portions of the lake and filling in of other parts have led to the reduction of the lake area at mean sea level from 252 km^2 in 1989 to 172 km^2 in 1920 to 137 km^2 in 1965 to 63 km^2 in 2000.

The annual rainfall on the lake was estimated as 0.145 m and the annual evaporation as 0.87 m (Shafei, 1952). The drainage flow to the lake has been recently estimated as $0.435 \times 10^9 \text{ m}^3 \text{ year}^{-1}$. Most of this volume is sanitary and industrial drainage water, some of which is drained into the lake without being treated due to the inadequacy of the existing plants. The organic material in the lake water is high (in the order of 50%), except in the northwestern and southwestern sections where it ranges from 4.7% to 6.3%. It has been suggested to begin with clearing the lake from the heavy deposits accumulated in it, removing the surface and submerged plants crowding the lake, draining water into the lake after treating it and stopping filling in any new parts of the lake.

Lake Qārûn, Egypt. The Fayoum Depression is in the Western Desert of Egypt. North of the depression lies Lake Qarful, which is the lowest part of the depression. The lake is situated between $29^\circ 24'$ and $29^\circ 32' \text{N}$ latitudes, and $30^\circ 24'$ and $30^\circ 49' \text{E}$ longitudes. It is an inland, isolated lake having an elongated shape and a surface area of 240 km^2 . The average length, width, and depth of the lake are 40 km, 5.7 km, and 6 m, respectively. The normal water level is about 44 m b.m.s.l. corresponding to

a capacity of $960 \times 10^6 \text{ m}^3$. Up to 1973, the lake served as out-fall escape to all drainage water of the agricultural land of the Fayoum Province. Since then, 30% of this water has been diverted to Wadi el-Rayyan Depression, which lies in the Fayoum Depression. The inflowing drainage water is mostly exhausted by evaporation from the lake. The annual rainfall and evaporation, averaged over the period 1960–1972, were 0.009 and 1.725 m, respectively. The average depth of drainage water for the same period was 2.036 m. Considering a net seepage flow of $66 \times 10^6 \text{ m}^3 \text{ year}^{-1}$, one can draw the water balance of the lake for the period 1960–1972, which indicates an annual rise of 4.3 cm or $10.34 \times 10^6 \text{ m}^3$. This figure agrees with the recorded average rise of 3.62 cm year^{-1} for the said period. The results obtained by Mankarious (1979) continued until 1978 to cover a period of 5 years after the inflow of the drainage water to the lake has been reduced. Ali et al. (2000) continued the study further up to 1996. The change in water level in the period 1860–1996 is presented in Figure 4.

Drainage canals carry annually 0.5 Tg of salt to lake Qārûn. As no salt leaves the lake, the water quality is rapidly deteriorating. The annual mean salinity for the years 1906, 1931, 1970, 1989, and 1996 was 14.0, 34.3, 39.6, 45.0, and 50.0 dS m^{-1} , respectively. One should not forget that the salinity of the Nile water is 0.4 dS m^{-1} and of the Mediterranean Sea is 25 dS m^{-1} . It is expected that the quality of the lake water by the year 2020 will be hazardous due to its high level of salinity causing disastrous impairments to agriculture, fishing, and tourism.

While water temperature at any particular depth varies over the season, it is only in summer that any appreciable stratification could be observed (0–4 m vs 5–8 m). By not including the summer thermal stratification, one can conclude that the lake can be considered as isothermal with well-mixed temperature (Ali et al., 2000).

Arab Region, Lakes and Reservoirs, Figure 4 Changes in water level of Lake Qārûn over the past century (By permission of Ali et al., 2000).

Qattara Depression, Egypt. The Qattara Depression, an under-sea-level depression, ranks next to the depression of the Caspian Sea in its largeness. Its deflated basin is the outcome of wind activity. The depression is situated roughly halfway between the Nile Valley and the Egyptian-Libyan border (Figure 3), with a total length from ENE to WSW of almost 300 km. The depression is bounded to the north and west by steep escarpments with a difference of elevation of 200 m. The shortest distance between the depression and the Mediterranean Sea near the town of Alamein is 80 km. The surface area of the depression at sea level is about 20,000 km² decreasing to 13,500 km² at 50 m b.m.s.l. The volume of contents at m.s.l. is about $1,200 \times 10^9$ m³. The eastern part of the depression is more shallow and narrow than the western and central parts. The deepest point of the depression is about 133 m b.m.s.l.

The area occupied by the depression is dry. The average freshwater evaporation as estimated by Flohn and Wittenburg (1980) using four methods, Dalton, heat budget, Penman, and Mcilroy, is 1.75 m. Several studies have been conducted with the aim of connecting the depression to the sea through a system of lined canals and tunnels so as turn the depression to a saltwater lake. To reach the design storage level of 50 m b.m.s.l., which can be reached within 16–20 years after the project starts, the inflow discharge should vary from $1,200 \text{ m}^3 \text{ s}^{-1}$ in the first half of the filling period to about $750 \text{ m}^3 \text{ s}^{-1}$ in the second half. The latter inflow rate will be balanced by the outflow, which is evaporation from the newly formed lake. The end result of those studies is to examine the feasibility of utilizing the head difference (50 m) to generate hydropower for the industrial development in Egypt.

Hydrochemical studies have proven that the Mediterranean water has low nutrient content. In 1976–1977, the nitrate–nitrogen concentrations were 0–23 mgL⁻¹ at the surface and 0–6 mgL⁻¹ at 100 m depth. The phosphate concentrations too were 0.3–3 mgL⁻¹ at the surface and 0.3–3 mgL⁻¹ at 100 m depth. Zero concentration indicates that the nutrient supply at times is locked up in organic matter. Only Silica exhibited a clear seasonal variation with a distinct winter minimum. The oxygen concentrations varied from down to half saturation in deep waters to full saturation in surface waters (UNGI Report No. 62, 1985).

In conclusion, the studies, which lasted from 1916 up to the 1980s and later, did not lead to any conclusive results except that the environmental assessment has not revealed any serious objections to the implementation of the project. The effects of the project on the groundwater levels, flows, and chemical and other characteristics remain, however, one of the major obstacles that need to be solved before any definite decision can be taken.

Al-Tharthar Depression (Reservoir), Iraq. The Tharthar depression is a natural depression that has become since 1956 a fresh water reservoir. Since then, it

has been rehabilitated in 1972 and 1976. The depression, which is slightly deeper than 3 m b.m.s.l., lies between the Euphrates and Tigris River. Its surface area increases from 400 km² at sea level to 955 km² at 25 m a.m.s.l. and further to 1,826 km² at 50 m a.m.s.l. to reach 2,460 km² at 62 m a.m.s.l. The inflow to the reservoir comes from Wadi al-Tharthar and the excess of the Tigris flow above a certain limit. The water in storage is diverted to the Euphrates in times of deficit. The reservoir is designed for irrigation and flood control purposes. The monthly flow of the Wadi Tharthar and the surrounding watersheds is: 20, 35, 30, and 15, all in 10^6 m^3 , for December, January, February, and March, respectively. The respective mean monthly rainfall is 30, 40, 40, and 30 mm. Evaporation varies from 80 mm in January to 400 mm in July. The normal and maximum retention levels and the dead storage level are 62, 65, and 42 m, respectively. The design capacities are $77.6 \times 10^9 \text{ m}^3$ and $85.4 \times 10^9 \text{ m}^3$ for the normal and full reservoir levels, $38.5 \times 10^9 \text{ m}^3$ for live storage, and $7.8 \times 10^9 \text{ m}^3$ for surcharge storage.

The monthly average solute concentrations of the reservoir water ranged from 1,990 to 2,240 ppm for the period 1983–1984. In order to detect the variations in water quality along the Tharthar-Euphrates channel (Figure 5), water samples were collected and analyzed for the major cations K, Na, Mg, and Ca, and anions Cl, SO₄, and HCO₃. The average solute concentration for the channel water during the same period ranged from 1,980 to 2,300 ppm. The results have also shown that there is no significant relationship between the solute concentration and the water discharge. The rate of suspended material transported through the channel is quite limited and it too has no relationship with water discharge (Al-Dabbas and Al-Jiburi, 1986).

Reservoirs in the Arab region

The Arab countries, at least some of them, are crowded with dams, consequently a large number of storage reservoirs. Most of these dams are small, low dams. The subsections given below present in brief some of the main features characterizing some of these reservoirs.

Storage reservoirs in Morocco. Moroccan wadi basins are equipped with a fairly large number of dams for irrigation and hydropower development. Besides, there are several dams under construction and/or planned for construction in the various wadi basins. A data summary of the existing reservoirs in Oum er-Rebia and Sebou Basins is given in Table 2.

Idriss-I reservoir is the largest storage work in the Sebou Basin. Its filling was completed in 1973. The long-term annual rainfall at a location near the reservoir is about 620 mm, most of which falls in the months from September to June. The Colorado Pan evaporation at El-Kansara reservoir on Wadi Beth ranges from 47 mm in January–February to 183 mm in July–August, with a total of $1,283 \text{ mm year}^{-1}$. The mean annual discharge of Wadi

Arab Region, Lakes and Reservoirs, Figure 5 Location map of Al-Tharthar Depression, Iraq.

Al-Masierah	Wadi Oum er-Rebia	1979	2,724	1,360
Lalla Takarcost	N'ffis	N.A.	78	65
Ayet Shwarit	Wadi al-Akhdar	1988	270	350
Dashr el-Wadi	Wadi Oum er-Rebia	1990	740	485
<i>Sebou Basin</i>				
Kansara	Wadi Beht	1935	272	210
Idriss-I	Wadi Inaouene	1973	1,270	990

Inaouene at Azib es-Soltane (1934–1988) station was $62.8 \text{ m}^3 \text{ S}^{-1}$. The normal full storage level is 217 m a.m. s.l. corresponding to about $1.1 \times 10^9 \text{ m}^3$ useful storage. The difference between this amount and the gross capacity is allocated for dead storage. Further development of the Sebou Basin, particularly to protect the Rharb Plain from the floods originating from the Sebou and its tributaries,

has prompted a fresh review of all existing and planned reservoirs in the basin.

Storage reservoirs in Syria. According to Water Authorities in Syria, the sum of the capacities of existing, under construction, and planned for construction reservoirs is $12.07 \times 10^9 \text{ m}^3$, of which the Euphrates (Assad or

Ath-Thawra) Reservoir alone has a total storage capacity of $11.6 \times 10^9 \text{ m}^3$, that is, 96.1% of the grand total storage capacity. The dam construction was completed in 1974. It is 40 m high and has a surface area at full storage level of 625 km^2 . As the three countries (Turkey, Syria, and Iraq) sharing the Euphrates River have not yet resolved their conflicts, we shall present here the reservoir water balance using the original design data.

The catchment area of the reservoir is $64,100 \text{ km}^2$, the reservoir precipitation and evaporation are 0.28 and 2.0 m year^{-1} , respectively, and the runoff coefficient is 10%. The inflow to the reservoir

$30.01 \times 10^9 \text{ m}^3 \text{ year}^{-1}$ is the sum of the inflow from the springs, 1.6×10^9 ; groundwater inflow, 0.4×10^9 ; the flow of the Euphrates received from the upper reaches of the river basin, 26.8×10^9 ; and the surface runoff, 1.21×10^9 , all in $\text{m}^3 \text{ year}^{-1}$. As the mean annual flow estimated from the old flow measurements at Husseiba on the Syrian-Iraqi border was $23.61 \times 10^9 \text{ m}^3$, the difference between the inflow and the outflow shows that Syria benefits from the reservoir by $6.4 \times 10^9 \text{ m}^3 \text{ year}^{-1}$.

Storage reservoirs in Jordan. Jordan has a relatively large number of storage works under construction or planned for construction in addition to the already existing dams/reservoirs. In view of its limited water resources, however, storage reservoirs in Jordan are of small effective capacity. Table 3 gives some of the particulars of the existing dams/reservoirs with total capacity larger than $5 \times 10^6 \text{ m}^3$ (Malkawi and Abdulla, 1997; Al-Kharabsheh and Ta'any, 2005). The sum of the total capacities of the reservoirs listed in Table 3 counts to 82% of the total capacity of all existing reservoirs and to 64% of the existing and under construction reservoirs.

The survey published in 1997 lists Al-Wahda dam under the group of Dams yet to be constructed. The idea goes back to 1956 to store the waters of the Yarmouk River at Maqarin near Irbid where the mean river flow is $273 \times 10^6 \text{ m}^3 \text{ year}^{-1}$. According to some agreement between Jordan and Syria, the construction of some preliminary works was carried out and completed in 1989. The strong opposition of Israel to the implementation of the project has brought it to a halt (Murakami and Musiaki, 1994).

Storage reservoirs in Egypt and the Sudan. As the Nile River system is the major water supplier to Egypt and the

Sudan, and the management of this source is done jointly between these two countries, particulars of the storage reservoirs are listed together in Table 4. The High Aswan Dam (HAD) is a long-term storage work aiming at full control of the river flow. The reservoir at storage level 170 m a.m. s.l. has a surface area of $4,308 \text{ km}^2$. As evaporation alone is in the order of 2.5 m year^{-1} the total loss of water at the said level can be estimated as $11 \times 10^9 \text{ m}^3 \text{ year}^{-1}$ reducing the long-term mean natural flow of the Nile at Aswan from $84 \times 10^9 \text{ m}^3 \text{ year}^{-1}$ to $74 \times 10^9 \text{ m}^3 \text{ year}^{-1}$. As the sum of the annual volumes of river water used by Egypt and the Sudan in the pre-dam condition was $52.5 \times 10^9 \text{ m}^3 \text{ year}^{-1}$, the gain due to storage is $21.5 \times 10^9 \text{ m}^3 \text{ year}^{-1}$. This amount has been divided such that $7 \times 10^9 \text{ m}^3 \text{ year}^{-1}$ is allocated to Egypt and $14.5 \times 10^9 \text{ m}^3 \text{ year}^{-1}$ to the Sudan, bringing the respective shares of Egypt and the Sudan to $55.5 \times 10^9 \text{ m}^3 \text{ year}^{-1}$ and $18.5 \times 10^9 \text{ m}^3 \text{ year}^{-1}$. These shares are proportional to the populations of the two countries by the time the reservoir was put into operation.

The reservoir formed by the Aswan High Dam is a multipurpose storage work aiming at providing water for newly cultivated lands, developing hydropower, protecting land and properties against floods, and improving inland navigation. On the other hand, the reservoir failed to modify the harsh climate and environment of the surroundings. Instead it resulted in inundation of certain areas in Nubia and many of its inhabitants had been forced to migrate. Additionally, the sediment flow downstream of the dam has stopped and substituted by artificial fertilizers, which require a lot of hydropower to manufacture. Vast tracts of the land downstream of the reservoir suffer from poor drainage conditions, and the sediment-free flow condition is causing the retreat of the seashore line and disappearance of certain species of sea fish.

Recharge reservoirs in the Arabian Peninsula. Some States of the Arabian Peninsula have been for quite some time embarking on dam construction programs to utilize as much as possible the surface water runoff and to enhance a better management of their limited water resources. The number of dams constructed from the mid 1980s to the mid 1990s has reached 265 as specified in Table 5. The advantages of the artificial recharge reservoirs are twofold: water conservancy and mitigation of the impact of rainfall variability on agriculture. Due to major differences in topography and relief of the ground, one finds that the majority of dams in Saudi Arabia and

Arab Region, Lakes and Reservoirs, Table 3 Data of some of the storage reservoirs in Jordan

Dam/reservoir	Year of construction	Location	Dam height (m)	Effective capacity (10^6 m^3)	Total capacity (10^6 m^3)

Country	Number of constructed dams	Range of storage capacity, 10 ⁶ m ³	Number of dams under construction or planned to be constructed
Saudi Arabia	190	0.01–32.5	9
United Arab Emirates	35	0.25–18.5	5
Yemen	17	0.50–369	12
Oman	14	0.01–12.5	32
Total	256	0.01–369	58

Yemen are in mountainous regions because of the availability of surface runoff generated by the frequently occurring rain events. Differently, most of the recharge dams in Oman and the United Arab Emirates are built on wadi channels in flat areas, especially those close to the seacoast.

Most of the recharge reservoirs in Saudi Arabia are designed to hold the flowing surface runoff in the particular wadi at the site where recharge of the underlying aquifer is desired. The recharge is supplied from a surface source of relatively large area. This method is often criticized on the grounds that the evaporation loss is high, and secondly the rate of infiltration into the aquifer decreases accumulation of silt and other deposits in the reservoir. The latter can be eliminated or reduced through periodic removal of these deposits. Some pieces of literature (e.g., Al-Hassoun and Al-Turbak, 1995) discuss the efficiency and management of such reservoirs.

ARAL SEA

Peter O. Zavialov
 P.P. Shirshov Institute of Oceanology, Russian Academy of Sciences, Moscow, Russia

Synonyms

Aralskoye more; Lake Aral

Definition

The Aral Sea is a major salty lake in Central Asia, situated approximately between 44° and 47°N, and 58° and 61°E, at the border of Uzbekistan and Kazakhstan, two newly independent states of the former Soviet Union.

Introduction

Until 1960, the Aral Sea was the world's fourth largest lake in area, yielding only to the Caspian Sea, Lake Superior, and Lake Victoria. At the time, the Aral Sea volume was 1,060 km³, the surface area was about 66,000 km² and the maximum depth was 64 m. The absolute lake level varied only slightly around 53.4 m above the ocean level.

The terminal lake was fed by two tributaries, Amudarya River and Syrdarya River, providing together for 56 km³ of freshwater inflow on the long-term average. At the

time, the Aral Sea was a brackish water body. Its salinity spanned around 10 g/kg and never exceeded 12 g/kg. Generally, the water mass of the lake was spatially uniform: Except the estuarine areas of the rivers, the difference between the surface and bottom salinities was merely a few tenths of g/kg. The seasonal cycling of salinity was largely negligible (e.g., Kosarev, 1975). At the same time, temperature demonstrated rather energetic variability, both spatial and temporal, at different scales. The seasonal range of the SST was over 25°C, and horizontal SST gradients often exceeded 6–8°C per 100 km. The vertical stratification of temperature was also typically strong: In the bottom part of the western trench (depths over 60 m), temperature remained nearly constant at 2–4°C throughout the year, while the near-surface water masses in summer were as warm as 23–25°C, forming a steep thermocline at 20–30 m depths. Hence, the density fields were mainly governed by temperature rather than salinity. In consequence of the mild vertical stratification of the pre-desiccation Aral Sea, the entire water body of the lake was fully ventilated down to the bottom in all seasons. Moreover, most of the Sea was oversaturated with oxygen. The overall average content of oxygen was 6.3 ml/l, or 101% of the saturation value, but oversaturation as high as 180% has been observed near the northeastern shore (Blinov, 1956). The conditions of the brackish, fully ventilate lake favored biodiversity – for example, the Aral Sea accounted for 5–10% of fishery catches of the USSR.

In 1960, the lake level started to drop continuously. It is generally believed that the shallowing was mainly anthropogenic, and followed an increase of water diversions from the tributary rivers for agriculture. Some data and models, however, suggest that the desiccation was triggered, at least partly, by natural climate variability (e.g., Bortnik and Chistyayeva, 1990). Paleoclimatic reconstructions indicate that the Aral Sea has undergone several similar shrinking episodes in the distant past, always followed by subsequent recoveries (e.g., Boomer et al., 2009).

Recent changes in the physical state of the lake

The Aral Sea's desiccation is known as one of the world's worst ecological disasters of the kind. By the date of this writing (October 2010), the total level drop was about 26.6 m. The Aral Sea has split into several separate water bodies, of which the most notable are the so-called Small Sea in the north and the Large Sea in the south (Figure 1). The latter consists of now almost separate western and eastern basins, connected through the narrow channel. Today, the western basin remains relatively deep (up to 38 m), while the eastern basin is extremely shallow (less than 2 m). Because of differential heating in summer, the shallow eastern basin is subject to very intense evaporation. This is why, in the last years, the salinity in the eastern basin was, generally, much higher than that in the western one. Overall, with its today's volume of only about 90 km³, including 50 km³ in the Large Sea and 40 km³ in the Small Sea, the lake has lost over 90% of its water (Figure 2).

The shrinking of the Aral Sea has been accompanied by a continuous salinity buildup. The most recent salinity figures available on the date of this writing (data obtained in August 2009) are 136 g/kg for the western Large Sea, and over 210 g/kg for the eastern Large Sea, constituting notable increase by respective factors of 13 and 21 since 1960. As to the Small Sea, in 2005–2006, the Kazakhstan authorities built a permanent dam isolating the Small Sea from the rest of the lake, and effectively trapping the

discharges of Syrdarya Rivers in the Small Sea. In consequence, the salinity in this part of the lake decreased and continues decreasing.

A key feature characteristic for the “new” state of the Aral Sea, in contrast with its regime prior to the desiccation onset and that at the initial stages of shrinking, is the vertical stratification. The first of the recent survey conducted in 2002 immediately revealed the salinity difference as high as 12 g/kg between the upper mixed layer (82 g/kg) and the bottom layer (94 g/kg). According to the available previous hydrographic data, namely, the data of 1990 (Bortnik and Chistyeva, 1990), the Aral Sea was still well mixed at that time. We, therefore, can only conclude that the strong vertical stratification first appeared sometime between 1990 and 2002, and the exact dating is unknown. However, there are reasons to believe that this may have happened in 1996–1997. The stratification continued to build up since then. It has been shown that the principal source of stratification in the western Large Aral is the water from the saltier, denser eastern basin, penetrating into the western lobe through the connecting strait and eventually accumulating in the deep layers (Zavialov, 2005, Zavialov, 2009). Typical vertical profiles of temperature and salinity in the deepest part of the Aral Sea (observed in August 2009) are shown in Figure 3. The near-bottom salinity maximum seen in this figure is attributed to the admixture of water from the shallow eastern basin.

Recent velocity measurements in the lake demonstrated that the basin-scale circulation of the Large Aral forms an anticyclonic gyre in the surface layer, and a cyclonic gyre in the bottom layer. Intense internal wave activity in the pycnocline, which may be an important mechanism of the lake mixing, was documented (Zavialov et al., 2009).

Aral Sea, Figure 1 Original shore line of the Aral Sea (as of 1960) superimposed on a recent satellite image of the lake (MODIS-Aqua scanner, July 5, 2010). The northernmost water body is the Small Sea, the western and the eastern basins of the Large Sea are seen in the southwestern part of the figure, interconnected through the narrow strait.

Other important issues

The desiccation resulted in significant alterations in not only physical state of the lake, but also its chemical regime. As mentioned above, prior to the desiccation onset

Aral Sea, Figure 2 The Aral Sea level drop (*fine curve*) and volume shrinking (*bold curve*) for 1950–2009.

Aral Sea, Figure 3 Vertical profiles of temperature (*right*) and salinity (*left*), typical for the advanced stage of the Aral Sea desiccation. August 2009, central part of the western basin.

in 1960, the entire Aral Sea was always saturated with oxygen. This situation continued through the initial decades of the desiccation in 1961–1991, but significantly changed sometime between 1991 and 2002. By the late 1990s, enhanced density stratification had arisen, largely impeding vertical mixing and ventilation. As a consequence, the bottom portion of the column turned anoxic and contained hydrogen sulfide. The H_2S contamination was first observed in 2002 (Zavialov, 2005) and persisted since then, at concentrations ranging from 5 mg/l to 80 mg/l, although intermittent ventilation episodes associated with winter convection were also documented (Zavialov and Ni, 2009). The depth of the upper limit of the sulfide-containing layer varied from 15 to 35 m.

Even before the desiccation onset, the Aral Sea water already had rather peculiar salt composition, which was quite different from that of the ocean water, as well as many other saline lakes. The contemporary desiccation has led to significant additional alterations of the chemical composition. During the desiccation, the salt composition of the Aral Sea has been subject to continuous changes because of chemical precipitation accompanying the salinity buildup (Bortnik and Chistyeva, 1990). As the salinity increased initially, the first compounds to precipitate were the calcium and magnesium carbonates. The subsequent salinization led to the massive precipitation of gypsum. According to (Bortnik and Chistyeva, 1990), this major process started when the salinity exceeded 28 g/kg, i.e., in the late 1980s. Processes which took place at higher salinities include the precipitation of mirabilite and halite (Rubanov et al., 1987). The total masses of minerals sedimented from the onset of the

desiccation through 2008 are estimated as follows: gypsum, 2.3 billion tons; mirabilite, 1.9 billion tons; halite, 0.4 billion tons; carbonates of calcium and magnesium, 0.2 billion tons.

Obviously, the large-scale precipitation of the salts must have led to significant changes in the salt composition of the remaining water mass of the lake, so that today's figures differ considerably from those known for the pre-desiccation period. The relative concentrations of the principal ions before and after the desiccation are shown in Table 1.

It is evident that the relative contents of the ions changed significantly during the desiccation. The most pronounced changes occurred with Ca^{2+} whose relative concentration decreased ninefold, from 4.6% to only 0.5%. Of course, this must have been expected, because the precipitation of both calcium carbonate and gypsum consumes calcium. The sulfate ion, also consumed in gypsum precipitation, decreased in relative content as well, from 31% to 23%. In contrast, the relative content of Cl^- grew from 34% to 43%. In consequence, the mass ratio $\text{SO}_4^{2-}/\text{Cl}^-$ decreased from 0.90 to 0.52, i.e., by 42%. Also strongly reduced by about a factor of 2.5 is the content of the bicarbonate ion HCO_3^- which was consumed by the formation and precipitation of calcium and magnesium carbonates. The relative content of sodium increased from 22% to 25%.

The abrupt changes of the physical and chemical conditions of the Aral Sea led to severe consequences for the biological systems of the lake. The present situation is less alarming in the Small Sea, where even fisheries are now recovering. However, in the principal part of lake, the Large Sea, the last specie of fish (flounder)

Aral Sea, Table 1 Relative contents of the principal ions in the Aral Sea water in 1952 and 2008

Ion	Cl ⁻	SO ₄ ²⁻	HCO ₃ ⁻	Na ⁺	Mg ²⁺	K ⁺	Ca ²⁺
Content (%) 1952	34.5	31.1	1.5	21.9	5.2	1.2	4.6
Content (%) 2008	43.3	22.6	0.6	24.8	6.7	1.5	0.5

was extinct in 2003. Nonetheless, despite the enormous mineralization, the Large Sea is still alive – some biological communities demonstrated high resistibility to the salinity growth. According to (Sapozhnikov et al., 2008), over 40 species of microalgae currently populate the Large Sea. The dominant specie in zooplankton is *Artemia parthenogenetica*, whose total stock in the Large Sea is as high as 50,000 t (Arashkevich et al., 2009).

The ongoing Aral Sea crisis also involves a variety of serious problems ranging from air pollution and deterioration of water resources to human health issues and significant challenges to the regional economy.

ARCH DAMS, DEVELOPMENT FROM CUT-STONE ARCHES TO MODERN DESIGN

Hubert Chanson, D. P. James
 School of Civil Engineering, The University of
 Queensland, Brisbane, QLD, Australia

Introduction

Dam designs may be divided into three main types: gravity structures relying on their weight for stability, arched structures using the abutment reaction forces, and buttress dams. Historically, the first dams were earthfill and rockfill embankments, for example, Sadd-El-Kaffara (Egypt BC 2800–2600), Marib (Yemen BC 750), Panda Wewa (Sri Lanka BC 400–300), Cornalvo (Spain AD 150–200). Masonry gravity dams were built at sites where good quality stones were available, for example, Khosr river (Iraq BC 694), Al-Harbaqa (Syria AD 132), Kasserine (Tunisia AD 100–200). Note that concrete and stone masonry dams are commonly called “gravity dams.” Sometimes, the dam wall was reinforced by masonry buttresses, for example, Alcantarilla (Spain BC 200–100), Proserpina (Spain AD 130). Later designs included arch dams, relying on the abutment reaction forces to resist the resulting water pressure force. A related design is the multiple-arch buttress dam, consisting of a series of arches supported by buttresses. Smith (1971) and Schnitter (1994) presented comprehensive treatises on the history of dams. However, the arch dam design was rare up to the late nineteenth century, and the historical development of such dams received less attention, with one notable exception (Schnitter, 1976).

The present contribution shows that the historical development of arch dams progressed during five periods: the Roman arch dams (First centuries BC and AD), the Mongol dams (fourteenth and fifteenth centuries), some advanced masonry dams in the early nineteenth century (1804–1856), the Australian concrete arch dams (1880–1896), and the modern arch shapes at the beginning of the twentieth century (1903–1928).

Terminology

It is inadequate to define a dam as curved or arched because it does not identify the relative importance of the gravity and the abutment forces in providing stability. Such a dam should correctly be called a curved-gravity, thick-arch or thin-arch structure. A *curved-gravity dam* is primarily a gravity structure relying on its weight for its stability, and the wall curvature adds little to its stability. By contrast, an *arch dam* would be unstable without the contribution of the abutment reaction forces.

A *thick-arch dam* relies both on its weight and on the abutment reaction for its stability. A *thin-arch dam* is a leaner structure relying predominantly on the abutment reaction forces for its stability; typically the ratio of the base thickness to the dam height (E/H) is less than one third. Practically, the arch dam design is well adapted to narrow gorges, and it produces substantial savings in costs compared to a gravity dam.

The basic arch dam shapes are the constant-radius arch, the constant-angle arch and the double-curvature arch with increasing complexity. The *constant-radius arch* design, also called the single-radius arch, is a cylindrical shape (Figure 1). The upstream face is usually vertical while the downstream face is battered. The *constant-angle arch* design is a variable-radius arch. The design is based on a constant central opening angle, with the arch radius increasing from base to crest (Figure 1). The concept was first introduced by Albert G. Pelletreau (1843–1900) in 1879 (Pelletreau, 1879). It results in considerable saving in construction material, compared to the constant-radius arch design. Lars R. Jorgensen (1876–1938) who applied the concept demonstrated that the dam contained minimum material for an optimum opening angle of 133.6° (Jorgensen, 1915); he added however that “the use of a smaller central angle [...] might be more economical, and 120° or even less [...] might give very satisfactory results.” The *double-curvature arch* design, also called spherical dome or cupola, has a more complex shape, and vertical curvature is introduced. The shell design results in saving in concrete but requires more technical skills than for a constant-angle arch dam.

Roman arch dams

The first arch dam is probably the Roman dam at Glanum, built during the first century BC to supply water to the Roman town (Table 1). The Roman dam was rediscovered in 1763 by Esprit Calvet (Benoit, 1935; Goblot, 1967). A recent study by Augusta-Boularot and Paillet (1997) indicated that the dam was made of cut stones held together with crampons and finished with waterproof cordon joints. The site was well selected, and the wall abutments were cut in the rock. A newer dam was built in 1891 at the same place, above the Roman dam foundation, and it still stands today. Another unusual Roman dam was the Esparragalejo dam, near Merida (Table 1). Built around the 1st century AD for irrigation purposes, the structure was a multiple-arch buttress dam, 5.6-m high and 2-m thick at base with circular arches.

Discussion

The Romans built gravity embankment dams (e.g., Alcantarilla, Spain BC 200–100; Proserpina, Spain AD 130), straight masonry gravity dams (e.g., Al-Harbaqua, Syria AD 132), and curved-gravity dams (e.g., Kasserine dam, Tunisia, AD 100? (Saladin, 1886), Çavdarhisar dam, Turkey (Schnitter, 1994)). But the dam at Glanum was unique. It was a slender thin-arch dam ($E/H = 0.265$). The authors hypothesize that the arch dam design

Arch Dams, Development from Cut-Stone Arches to Modern Design, Figure 1 Comparative sketch of single-radius and constant-angle arch dams.

was introduced because the site was favorable to a masonry dam but nearby construction materials were scarce.

The arch technique was applied by the Romans to sewers, aqueducts and bridges, although there is no evidence of scientific design rules. Professor C. O'Connor suggested that, for Roman bridges, the ratio of arch rib thickness to span was about $1/10$ for spans less than 15 m and could be reduced down to $1/20$ for greater spans (O'Connor, 1993, pp. 168–169). Interestingly, the ratio of dam wall thickness to arch curvature radius was between $1/10$ and $1/7$ at Glanum, i.e., close to Roman bridge dimensions.

For completeness, some researchers (Schnitter, 1979; Augusta-Boularot and Paillet, 1997) suggested the existence of further Roman arch dams, e.g., Kasserine (Tunisia), Dara (Turkey), Çavdarhisar (Kütahya, Turkey), Örükaya (Çorum, Turkey). The Çavdarhisar and Örükaya dams were flood retention structures; their scour outlet system had cross-section areas of 11 and 3 m², respectively (Stark, 1957–1958). A reanalysis of these structures demonstrated that Kasserine, Çavdarhisar, and Örükaya were curved-gravity dams. In the particular case of Dara, the Byzantine historian Procopius (sixth century AD) indicated a curved dam, possibly as at Kasserine, and no remain is visible.

Notes:

Date: construction period (*underlined completion date*); 300/600: construction in 300, heightening in 600.

Design: VA = arch; VA-a = thick arch, VA-b = thin arch, MV-CB = multiple-arch buttress.

Notation: E : dam base thickness; e : dam crest thickness; H : dam height above foundation; L : arch dam crest length; R : radius of curvature of arch wall; θ : arch opening angle; (1) after first dam heightening; (?) : uncertain data.

Mongol arch dams

During the thirteenth century, the Mongols invaded and settled in Iran where they built several large dams, for example, the Saveh dam was a gravity dam built in AD 1285 ($H = 25$ m, $L = 65$ m). Around the fourteenth century, they built also some arch dams (Table 1). The Mongol arch dams in Iran had thick-arch walls, and they were significantly higher than the Roman dams. The first arch dam (Kebars, AD 1300) was heightened to 26 m around AD 1600, while the Kurit dam was 60-m high before heightening (Goblot, 1965, 1973). The Kurit dam was extraordinary, having the very-low crest length to dam height ratio L/H of 0.42 after heightening (probably less prior). It is interesting to note that these structures were used for several centuries. Several dams were still standing in the 1970s, although some were subjected to foundation failures, e.g., Chabb Abbasi. The complete upper portion of the dam wall was still standing in the 1970s despite the missing foundation (Goblot, 1973). In the authors' opinion, this highlights the soundness of the arch wall design and the quality of the masonry work. The Mongol dams were further equipped with sophisticated outlet systems (e.g., Kebars, Kurit).

Discussion

Some transfer of expertise on arch dam design might have taken place from the Romans to the Iranians. After the defeat of Valerian's army in AD 260, 70,000 Roman soldiers were captured and transported to Persia where they were forced to work. The Roman army was often involved in large-scale civil engineering works, in particular aqueduct constructions (Fevrier, 1979; Leveau, 1991), and it is likely that it was also involved in dam construction. The Roman prisoners built bridge-weirs and dams in Iran. Examples of bridge-weir include Dezful and Shustar, and an example of dam is Ahwaz (e.g., Smith, 1971; O'Connor, 1993; Schnitter, 1994). Shustar dam is also called Band-i-Kaisar or "Dam-Bridge of Valerian" (O'Connor, 1993). Ahwaz dam, also called Ahwaz weir, was a 900-m long masonry weir on Karun river. Some structures, for example, the Shustar bridge-weir, were still in use when the Mongols invaded in Iran. There is however no proof that the Mongols were aware of the Roman arch dams.

Both the Roman and Mongol dams in Iran were milestones in arch dam development. From the fourteenth century up to the beginning of the nineteenth century, the arch dam development was scattered and disparate. An arch dam was built in Italy at Pontalto in 1612, and the structure was heightened more than six times over the next 270 years from 5-m to 37.8-m. In Spain, Don Pedro Bernardo Villareal De Berriz (1670–1740), a Basque nobleman, designed and built one single-arch and four multiple-arch dams with vertical circular arches in the 1730s. They were low-head structures used for water power purposes, and four of them are still in good condition (Smith, 1971).

Masonry arch dams in the early nineteenth century

During the first part of the nineteenth century, the arch dam design was dominated by four large structures. These were the Meer Allum (India), Jones Falls (Canada), Zola (France), and Parramatta (Australia) dams (Table 1).

In India, Henry Russle, Royal Engineers, built the extraordinary Meer Allum (Mir Alam) dam with a 10-Mm^3 water storage capacity around 1804; see, for example, Engineering Record (1903), Schuyler (1909), Smith (1971), Schnitter (1994). The multiple-arch dam was built to supply water to Hyderabad, and it is still in use. It consists of 21 semicircular vertical arches with span ranging from 21.3 to 44.8 m.

In Canada, Lieutenant-Colonel John BY (1779–1836) built several curved masonry dams between 1827 and 1832 as part of the Rideau waterway system. One structure, the Jones Falls dam, was a true arch dam (Legget, 1957–1959; Smith, 1971; Schnitter, 1994). Completed in 1831, the 18.7-m high dam was a constant-radius arch wall, 8.4-m thick at base (Table 1). The dam is still used today for hydropower and navigation purposes.

François Zola (1795–1847) designed two arch dams in 1832 for the water supply of the city of Aix-en-Provence, France (Coyne, 1930, 1956). One, the Zola dam, was built between 1847 and 1854. It was the first arch dam design based on a rational stress analysis (Schnitter, 1994). The reservoir was used as a town water supply until 1877, and the dam is still in use for flood retention (Figure 2).

One of the first significant hydraulic structures in Australia was the Parramatta dam near Sydney (Figure 3, Table 1). Built between 1851 and 1856, the 12.5-m high arch dam was designed by P. Simpson (1789–1877), E.O. Moriarty (1824–1896), and W. Randle (Ash et Heinrichs 1996). It was a constant-radius arch with a cylinder shape, and it was heightened by 3.35-m in 1898 under the supervision of Cecil West Darley (1842–1928) (Wade, 1909).

Arch Dams, Development from Cut-Stone Arches to Modern Design, Figure 2 Zola dam, Aix-en-Provence, France, in June 1998.

Arch Dams, Development from Cut-Stone Arches to Modern Design, Figure 3 Parramatta dam, Sydney, Australia on September 27, 1999.

Discussion

All four structures were constant-radius arches built in cut-stone masonry. It is generally believed that the thickness of cylindrical arch was calculated using the thin cylinder formula because the concept was familiar at the time to engineers involved in shell and ship hull calculations.

It is worth noting that three dams were built in the British empire. Two structures were designed by Royal Engineers: the Meer Allum multiple-arch dam (1804?) and Jones Falls thick-arch dam (1831). It is possible that these designs influenced the Australian engineers with a transfer of expertise taking place through Royal Engineers. The Royal Engineers in India had a strong involvement in water supply systems, and they were sometimes called upon in Australia. The authors believe that the Royal Engineers in India were aware of the successes of Meer Allum and Jones Falls dams and they might have advised Australian engineers.

The four masonry arch dams are still in use for water supply (Meer Allum), hydropower (Jones Falls), flood retention (Zola), and recreation (Parramatta). Their long-lasting operation demonstrates the soundness of design and the quality of the masonry construction.

Concrete arch dams in Australia

Built near Warwick (QLD), the 75-miles dam was a water supply for steam locomotives (Chanson, 1999). The first dam was designed by Henry Charles Stanley (1840–1921). It was a concrete arch, 5.04-m high, 1.07-m thick at crest, and 2.784-m at the base. The dam was equipped with an overflow spillway, a scour outlet and a water outlet feeding a water tank located below beside the railway line. In 1900–1901, the dam was heightened to 8–10-m under the supervision of STANLEY. The enlargement included the addition of three concrete buttresses (Figure 4). The 75-miles dam in 1880 was the oldest concrete arch dam built in Australia, and possibly the world's oldest concrete arch dam. It was the second arch dam completed in Australia as well as the second dam built entirely of

concrete in Australia with a vertical upstream face and battered downstream face (1H:3.6V). The first concrete dam was the Lower Stony Creek dam near Geelong VIC completed in 1873 (Lewis, 1988; Harper, 1998).

Completed in 1896, Lithgow No. 1 dam was built as a town water supply and designed by C.W. Darley (Figure 5). The 10.7-m high dam was a concrete single-radius thin-arch structure with a vertical upstream face and battered downstream face (1H:3.6V). It was equipped with an overflow section and an outlet system. In 1914 or 1915, the dam was heightened by closing the spillway overflow section and adding new wing walls. A new overfall spillway was built. The dam was disused around 1983–84 because the reservoir did not have enough available head to feed the new wastewater treatment plant. It has been kept empty since 1986, and it is now used as a flood retention reservoir (Figure 5). Lithgow No. 1 dam was the first Australian thin-arch dam, and it is the world's oldest concrete thin-arch structure. The design by Darley became a standard, commonly called “Darley-Wade dam” design in Australia (Chanson and James, 1998b, 2002).

Between 1907 and 1909, Ernest Macartney de BURGH (1863–1929) built two thin-arch dams, de Burgh dam (1907–1908) and Barren Jack City dam (1908–1909), also called Barren Jack Creek dam, as part of the construction of the Burrenjack reservoir (Barren Jack NSW, 1927), also called Burrenjack or Barren Jack dam (concrete gravity structure, $H = 61$ m, $L = 233$ m) (Chanson and James, 1998b). First completed, de Burgh dam was built to supply water to the railway line supplying the construction site, also called Burrenjack or Barren Jack dam (concrete gravity structure, $H = 61$ m, $L = 233$ m). It was a reinforced-concrete single-radius thin-arch dam (Figure 6). The concrete wall was reinforced with 20-lb. rails, 1.52-m apart horizontally and 3.048-m apart vertically. The de Burgh dam was a true reinforced-concrete arch with rail reinforcement placed from toe to crest. The wall reinforcement was not a standard design feature of the Darley-Wade dams like the Lithgow No. 1 dam. With Hume Lake dam (see below), the de Burgh dam is the world's oldest reinforced-concrete thin-arch dam.

The oldest multiple-arch dam in Australia

Completed in 1897, the Junction Reefs dam is a multiple-arch dam, 18.3-m high (Figure 7). It was also called Junction Point Reefs dam or Belubula dam (Schulze, 1897; Schnitter, 1994). There are five elliptical arches, each with a 8.5-m span and a 60° lean. The dam foundation and outside walls were made of concrete while the arches and buttresses were built in brick. Brick construction was selected as the cheapest and quickest material to build for the arches, concrete being cheaper only for the foundation (Schulze, 1897). Curiously, the original design included six arches but the final design had only five arches because of delays in the brick-making. The arches were designed in the same way as bridge arches: “the arches were calculated in the same way as bridge [...] and the buttresses as

Arch Dams, Development from Cut-Stone Arches to Modern Design, Figure 4 75-Miles dam (Warwick QLD, Australia). (a) View from downstream of the dam with the three concrete buttresses (Photograph taken on 23 January 1998). (b) Details of the dam crest and buttresses (Photograph taken on January 23, 1998).

bridge piers” (Schulze, 1897, p. 171). Professor C. O’Connor commented that the arch shape and brick laying was unusual, the arch bricks being laid inclined parallel to the upstream arch face while the buttress elliptical shape was not easily understandable. Built to provide hydro-power for the nearby gold mine, the dam suffered heavy siltation and the reservoir is fully silted today. The design of Junction Reefs has been well known overseas (Wegmann, 1922; Smith, 1971; Schnitter, 1994).

Modern arch dam designs

The introduction of concrete as a construction material for arch dams marked a significant advance. Designers were able to consider complex curved shapes to minimize the construction material and the overall cost. The developments took place first in North America (Table 1).

Arch Dams, Development from Cut-Stone Arches to Modern Design, Figure 7 Junction Reefs dam (Lyndhurst NSW, Australia) (Photograph taken on December 28, 1997) View from the left bank.

Professor G.S. Williams (1866–1931) designed the world's oldest cupola dam (Figure 8). The Ithaca dam (New York, USA, 1903) was designed to be a 27-m high structure, but construction was stopped when the dam height reached 9-m because of local opposition (Schuyler, 1909; Wegmann, 1922). An interesting construction detail was the brick facing used as concrete formworks.

The oldest concrete multiple-arch dam was designed by John S. Eastwood (1857–1924). The Hume Lake dam (California, USA 1908) was built in the Sierra Nevada Mountains in 114 days (Wegmann, 1922)! The 206-m long 18.6-m high structure consisted of 12 circular arches (15.24-m span) inclined at 58° with the horizontal and vertical in the upper 4.88-m section. The concrete reinforcement included old logging cables (over 12 km) and railroad scrap iron.

Lars R. Jorgensen designed the first constant-angle arch dam: the Salmon Creek dam (Table 1). (This is not strictly correct: Jorgensen (1915) mentioned a smaller constant-angle dam designed by an American H.F. Cameron in the Philippines around 1913–14. The 30-m high dam was used for Manila's water supply.) Completed in 1914, the Salmon Creek dam was 51.2-m high and the opening angle was 113° . The arch radius ranged from 44.96-m at base to 100.9-m at crest.

Another advanced design was the Coolidge dam (Globe Ariz., USA 1928). It was the first cupola-shaped multiple-arch structure. Consisting of three arches, it was designed and constructed by the US Bureau of Indian Affairs, and it is still in use for irrigation and hydropower.

Discussion

Although dams were built as early as BC 3,000, and concrete was used by the Romans, the world's first concrete dams were completed in 1872 : Boyds Corner (New York,

USA) built between 1866 and 1872 and Pérolles dam (Switzerland) built from 1869 to 1872. The Boyds Corner dam underwent a major refurbishment in 1990, with the construction of a new spillway (6.1-m wide flip bucket in the central dam section) and the use of post-tensioned anchors to increase the dam stability. Also called La Maigrauge dam, the Pérolles dam was heightening in 1909.

These two dams were followed by others, e.g., Lower Stony Creek (Australia, 1873), San Mateo (San Mateo CAL, USA, 1888), also called Lower Crystal Springs dam. All these were gravity dams. In the United Kingdom, the first mass concrete dam exceeding 15-m in height was the Abbeystead dam completed in 1881 (Binnie, 1987). In Hong Kong, the Tytam dam, completed in 1887, was a concrete gravity structure with masonry stone facing. The Sand River gravity dam, completed in 1906, was the first concrete dam in South Africa (Schuyler, 1909; Wegmann, 1922). Note that the first South African arch dam was completed near Johannesburg in 1898–1899 for mining purposes. In India, the first large concrete structure was the Periar (or Periyar) dam built between 1888 and 1897 near Madras (Schuyler, 1909). In 1870, Rankine's opinion was sought as to the dam profile. In his reply, Rankine extended the method of de Sazilly and Delocre for the design of gravity dam, first applied to the Gouffre d'Enfer dam (Delocre, 1866; Rankine, 1872). This design method is considered as the basic analysis of the stability of gravity dams. Altogether, the construction of concrete dams began in the 1870s and intensified at the turn of the century.

Historically, after the Roman and Mongol era, the arch design fell out of favor until the nineteenth century. The development of arch dams was later facilitated by the introduction of concrete as a construction material.

Arch Dams, Development from Cut-Stone Arches to Modern Design, Figure 8 Ithaca dam (New York, USA), photograph taken in 1998 (Courtesy of Mr G. Toombes).

The world's oldest concrete thick-arch and thin-arch dams were single-radius arches built in non-reinforced concrete. The designs were based on the thin cylinder formula (Wade, 1909; de Burgh, 1917). The Australian concrete arch dam design was acknowledged in Europe and in the USA (Schuyler, 1909; Wade, 1909; Wegmann, 1922; see also Smith, 1971; Schnitter, 1994). Wegmann (in the discussion of Wade, 1909) stated that, in his opinion, "the curved dams built [...] in New South Wales had been designed more logically" than any other arch dams or curved-gravity dams.

Masonry construction: cut-stone or concrete

The zenith of stone masonry dam construction was the 1850–1900 period, and the construction techniques were well documented (Wegmann, 1893; Creager, 1917). Why did the Australian engineers select concrete as dam construction material? In Australia, concrete was used for waterworks, weirs, and dams as early as the 1870s. By world standards, large and innovative concrete works were produced such as the great dome of the Melbourne

Public Library (1908–1913) which was the world's largest reinforced-concrete dome at the time (Lewis, 1988). Concrete construction for arch dams was selected because of the lower cost, the facility of construction by unskilled labor and the ease to build irregular shapes compared to stone masonry construction.

Concrete was the cheapest construction material at the end of the century. Darley (1900) estimated the total cost of Australian arch dam at \$8 per m³ of masonry (Cost in US\$ of the time, with an exchange rate of about £ 1 = US\$ 4.9 (Schuyler, 1909)) (Table 2). Table 2 shows that the cost of concrete dam construction dropped from the 1870s to the 1900s and became lower than that of stone masonry. Darley's choice was consistent, although in advance, with world-known dam engineers. In 1909, Schuyler indicated that cyclopean concrete and mass concrete were both cheaper than rubble masonry and obviously cut-stone masonry for dam construction (Schuyler, 1909, p. 204). In 1922, Wegmann discussed the masonry type for gravity dams: "As far as strength is concerned cut stone would be the best class of masonry for building a dam, but, on account of its great cost, it is only used at the faces and for [...] ornamental work at the top." (Wegmann, 1922, p. 49). (This marked a change of opinion. In 1893, he stated that "rubble masonry is undoubtedly the best material that can be used for building a dam" compared to cut-stone masonry, concrete or rubble (Wegmann, 1893).) Interestingly, a brick construction was selected at Junction Reefs dam as being cheaper than concrete at this particular site.

Another advantage of concrete over cut-stone is the ease of construction by laborers and horse carts. At Lower Stony Creek, "owing chiefly to the scarcity of masons, [...] the dam was built of concrete instead of masonry" (Gordon, 1875, p. 402). Australian concrete dams were built of blocks of stone set in concrete, a technique called plum concrete or cyclopean concrete. "Plum stones to the maximum size that can be handled by two men" were used (Darley, 1900, p. 56). "All the concrete [was] mixed by hand [and] wheeled into place in barrows and trucks" (Wade, 1909, pp. 10–12). The concrete was laid in 3-ft courses "held between mould-boards [formwork] 10 ft long by 3 ft 6 in. high" (Darley, 1900, p. 55). By comparison, stone masonry necessitated a skilled workforce (i.e., stonemason artisans) and a plant to carry stones. For example, a machinery capable to carry 2–6 t was used to handle and place the masonry blocks at Parramatta dam (Figure 3, Ash and Heinrichs, 1996, p. 13). The ease of construction contributed to the lower cost but also suited well a new continent without skilled manpower.

A third advantage of concrete construction was the flexibility of shape: "With concrete [...] labour is saved and concrete has the farther advantage that it can be rammed into any irregular cavity" (Dobson, 1879, p. 111). Dobson referred to the construction of the Lower Stony Creek dam. Concrete offered a flexibility of shapes and curved designs (e.g., cupola shape). The introduction of concrete as a construction material paved the way for

Arch Dams, Development from Cut-Stone Arches to Modern Design, Table 2 Masonry dam construction costs

Dam	Year of completion	Dam type, masonry type	Masonry volume (m ³)	Masonry cost (US\$/m ³)	Remarks

the newer modern designs : constant-angle and cupola arch dams, e.g., Ithaca (1903) (Figure 8).

The development of concrete dam construction under the leadership of Dobson and Darley marked the end of large stone masonry dam in Australia. From 1890, the highest large dam in Australia had been a concrete structure until the 1960s (Nimmo, 1966). An interesting parallel is the construction of masonry arch bridges. O'Connor (1974) showed that the construction of (notable) stone arch bridges came to a end basically in 1909. The historical development of bridges was characterized “by a complete cessation in the construction of major stone arches (c. 1909)” (O'Connor, 1974, p. 10). This date coincided with the construction of the Grafton bridge in Auckland (New Zealand) (completion 1910, 98-m clear span).

Multiple-arch dam design

The development of multiple-arch dams attracted some interest in Spain and Italy. Roman engineers built the oldest multiple-arch dam at Esparrageljo in Spain (Schnitter, 1994). In 1530, the architect Baldassare Peruzzi (1481–1536) proposed a multiple-arch dam for the reconstruction of a fishing pond reservoir in Siena, Italy (Schnitter, 1994, pp. 118–119). Turriano (1511–1585) recommended also the selection of multiple-arch dam “for use on large rivers” in his Codex (Garcia-Diego 1976). Villareal de Berriz built five multiple-arch buttress dams in Northern Spain around 1730.

In the nineteenth century, two significant structures were Meer Allum and Junction Reefs. Although Junction Reefs dam was smaller than Meer Allum, it incorporated new advanced features: elliptical arches and a sloping upstream face which enhances the dam stability. Further advances in designs were made with the Hume Lake and Coolidge dams.

Conclusion

The historical development of arch dams may be summarized in five stages (Table 1). The world's oldest

arch dams were built by the Romans in France and Spain. They were followed by the Mongols who built dams in Iran during the thirteenth and fourteenth centuries. However, it is not until the nineteenth century that significant progress in arch dam design was made. Four remarkable structures were the Meer Allum dam (India 1804), the Jones Falls dam (Canada 1831), the Zola dam (France 1854), and Parramatta dam (Australia 1856). All four of them are still in use today, and they demonstrated the soundness of arch dam design. Australian engineers pioneered the use of concrete as a construction material for arch dams. The world's oldest concrete arch dam was completed in 1880 : the thick-arch dam at 75-Miles. The world's oldest concrete thin-arch dam was the Lithgow No. 1 dam (1896). Both the 75-Miles and Lithgow No. 1 dams were made of non-reinforced concrete.

Modern arch dam designs were further developed in North America. The world's oldest cupola dam was completed in 1903 at Ithaca. The first constant-angle arch dam was completed in 1914. Modern multiple-arch design were completed in 1908 (Hume Lake) and 1928 (Coolidge). Since no major breakthrough has taken place. It is the writers' opinion that the introduction of concrete as construction material marked a major innovation in arch dam shape.

ARCTIC LAKES

Bent Hasholt

Department of Geography and Geology, University of Copenhagen, Institute of Geography, Copenhagen, Denmark

Definition

Lakes located in an arctic area. Geographically it is the area north of the Arctic Circle, 66°30'N; climatically it is the area north of the 10°C isotherm for the warmest month, provided the mean temperature of the coldest month is below 0°C.

Arctic lakes may be classified according to the formation of the depression where the lake is formed and the material in the bottom of the lake. Many arctic lakes owe their existence to carving of the landscape by previous or recent glacial erosion. This erosion may result in numerous lakes of all forms and depths; however, often an orientation determined by the direction of the ice movement is seen. Elongated deeper lakes may be formed by the melt water (tunnel valleys). Other deep lakes may be formed by the melting of buried dead ice. In recent tundra areas, lakes may be formed by periglacial processes such as thermokarst and development of pingos. The material of the bed is most often till of variable thickness or solid bed rock. In recent glaciated areas, lakes may be formed at the margin between a glacier or an ice cap and the surrounding landscape. If the ice at the margin is melted or lifted because of buoyancy of the lake water; such lakes can be tapped very fast causing large floods, so called jökulhlaups. On larger glaciers and ice caps, lakes may be formed in depressions into the surface, so that the boundary consists solely of ice. Such lakes may interact with the drainage system of the glacier or the ice cap and may also cause severe floods if the melting in the bottom removes the sealing to the internal

drainage system. The thermal conditions of arctic lakes are characterized by mixing and layering caused by the density maximum of water at 4°C. Another characteristic pattern in arctic lakes is the formation of an ice cover that can last from a few days to perennial. The ice cover influences the light conditions and the heat budget of the lake and thereby the biological conditions. Depending on the bathymetry of the lake and the initial chemical composition of the lake water, the formation of ice can cause significant annual variations in the chemical composition. In the case of shallow lakes, the ice formation can cause formation of brine that again may precipitate and develop layered sediment on the bottom of the lake.

Shortly after the disappearance of ice cover, the lake water attains a temperature of 4°C. Warming by solar radiation and advection of warm air heats the water, with surface temperatures up to 10–15°C, while the deeper parts remain at 4°C. A stable layer called the thermocline is formed between the two water masses. In the autumn, cooling causes a new isothermic situation. Then further cooling leads to ice formation when the surface water temperature is close to 0°C. When the lake is ice covered the water temperature rises slowly because of solar radiation penetrating the ice and by thermal heating from the bottom. Deposition of snow diminishes the penetration of solar radiation and insulates the lakewater reducing the heat exchange.

Ice thickness in Greenland and Arctic Canada is 1.5–2 m, increasing from south to north; a maximum of 2.5 m is recorded on Ellesmere Island. Freeze up begins early to mid-September while breakup begins June to August. Lakes in high arctic can be covered by ice for several years, e.g., Romulus Lake on Axel Heiberg Island, but normally at least a moat of open water near the shore is formed. Examples of climatic arctic lakes in Canada are Baker Lake in Nunavut and Lac Klotz on the Ungava Peninsula, both south of the Arctic Circle. Examples of High Arctic lakes are found on the Canadian Arctic Islands. In Greenland, arctic lakes are situated on both sides of the Arctic Circle. Examples of saline arctic lakes are found near Kangerlussuaq, West Greenland, e.g., Braya Lake and Limnea Lake.

ARTIFICIAL WETLANDS

Jesper Persson

Landscape Management, Design and Construction,
Swedish Agricultural University, Alnarp, Sweden

Definition

An artificial wetland is a wetland constructed by humans. It consists of a water body that has a water table above or near ground level, which is to a large extent covered by vegetation.

Since artificial wetlands are created, they differ from wetlands which are made through restoration or developed in a natural process. The difference between a created and a restored wetland is not obvious since restored wetlands also include those that historically have been diked out through draining in order to make space for agricultural land. These wetlands can be restored relatively simply by stopping or significantly decreasing the drainage. Thus, what many laymen regard as a created wetland is in many cases actually a restored one. In other words, if a wetland has existed at the place within the past 100–200 years, the present wetland is a result of restoration.

There are various ways of describing the difference between a wetland and a pond. From an engineering perspective, the difference is the quantity of vegetation, as a pond has minor vegetation while the opposite is true of a wetland (see [Urban Lakes and Ponds](#)). Size is unimportant, however, and may range from only a few square meters to several hectares. It may be added that systems such as infiltration beds and detention ponds are not considered to be artificial wetlands.

The main purpose of artificial wetlands is always to create added value for humans. Their function may be to purify water, reduce flooding, and increase the biological diversity. It may also be the case that an artificial wetland has arisen in connection with earlier industrial activity such as fish culture. Today, artificial wetlands are most often used as biofilters in order to purify wastewater from industries (such as dairy farms or pulp mills) and households, and also to treat leachate water from landfills. The increased focus on water purification by artificial wetlands has mainly been due to the fact that vegetation generally supports the purification, which makes them more effective than ponds. If the primary aim is to create a beautiful water body in a park, ponds are laid out more frequently than wetlands since one normally does not want to have too much vegetation. The same is true if the focus lies on creating a larger water volume for irrigation, as this results in a deeper pond that counteracts the establishment of vegetation.

Water entering a wetland may come from ground water, streams, swales, or pipes. The water is then either transported over ground level (i.e., surface-flow wetlands) or through the soil (i.e., subsurface-flow wetlands). In the

latter, the water is transported horizontally or vertically (i.e., vertical-flow wetlands). Generally, water entering vertical-flow wetlands is dosed or poured from the surface, however, it may also be applied from the bottom and then transported to the surface.

ASIA, LAKES REVIEW

Rhodes W. Fairbridge (Deceased), Lars Bengtsson¹
¹Department of Water Resources Engineering, Lund University, Lund, Sweden

Introduction

Asia has a total land area of 45,036,492 km² (17,388,686 square miles), not counting small islands, extending from the Arctic Ocean at about 77° 45'N to the East Indies (Indonesian Archipelago) at Roti Island, in the southern hemisphere (10°20' S), and from Asia Minor in the west (26°04' E) to the Bering Straits 169°40'W. Its principal W boundary is the Ural Mountains and Ural River to the Caspian Sea. The eastern limit of the Indonesian archipelago is generally taken to be the international boundary, Irian Barat and Papua New Guinea (141°E). The highest mountain in Asia (and the world) is Mt Everest, 8,848 m (29,028 ft), part in Nepal, part in China (Tibet). Its longest river, the Yangtze-Kiang (Chang Jiang), is 6,380 km (3,964 miles). (Geographical Information: *The Times Atlas of the World* (Bartholemew, 1999), 10th ed.)

Of the 18 major natural lakes in Asia, in terms of area, only one is located in the wet tropical zone, none in the arid, high-pressure belt, none in the subpolar arctic region, and only two in the Alpine–Himalayan orogenic belt. As a result, almost all the rest are to be found in the complex of block-faulted forelands, the central Asian orogenic systems and their intramontane depressions. Some of the smaller lakes are related to the strike-slip structures of the Middle East (Dead Sea, Galilee, etc.) or to the fluvial overflow associated with major rivers that include the Tigris, the Volga, the Amu-Dariya, and those of Siberia and China ([Figure 1](#)).

Two areas are covered with a peppering of very small endorheic drainage systems and isolated lakes, each of different origins though both are inherited from the last

glacial phase of the Pleistocene. The one is on the interior plateau of Tibet which is a very dry area in the rain shadow of the Himalayas to the S. and the Kun Lun to the N. The other is the tundras of N. Siberia where there is deep permafrost, which periodically melts near the surface and thus generates small lakes.

Finally, two lake systems must be characterized as unique:

- The Caspian Sea, which is a compound of an orogenic foredeep depression and an interior basin, also representing the largest inland body in the world
- The Tonlé sap, which has the remarkable characteristic of being filled by flow from the Mekong R. when the latter is in flood, and then reversing its flow during the dry season when the Mekong is low

Meteorologically, Asia is dominated by the seasonal alternation of the winter season when snow accumulation over Siberia and Tibet leads to a quasi-permanent high-pressure system that generates northerly winds in the Middle East, India, and NE airflows in China and the

East Indies. The latter become warmed in the tropics and eventually pass into the southern hemisphere as the wet NE Monsoon of the East Indies and northern Australia. In the summer season, this high pressure is replaced by low pressure systems that create the inward directing Asiatic Monsoon from the tropical part of the Indian Ocean. This brings the familiar wet Monsoon of India and S.E. Asia.

Besides the monsoon alternations there is the seasonal shift in prevailing westerlies and their jet streams. The winter flow brings the seasonal rains at the beginning of the year into the Middle East, Israel, Syria, Turkey, and Iraq, sporadically reaching as far as northern India. With summer, the jets weaken but may swing across northern Europe to northern Scandinavia and rarely touch northern Asia.

Natural lakes, geomorphic divisions

Epeirogenic basins and plains

- Caspian Sea*, the world's largest inland water body, is divided between Europe and Asia, and is partly in the Russian federation, Kazakhstan, Turkmenistan, Iran,

and Azerbaijan. It is 1,220 km (760 miles) in length, N-S. It covers 271,000 km² but is increasing today. The water is the so-called "caspi-brackish," that is, not salty like the ocean with its dominance of NaCl, but with NaSO₄ (and other salts). Its primary intake is from the Volga which drains central Russia but has no outlet at the present time. During the Pleistocene cold cycles, at times, its level rose to form a spillway in the Manych Depression north of the Caucasus to debouch into the Black Sea. Its total drainage area is 3,100,000 km² and capacity is 78,200 km³, having a maximum depth of about 1,025 m (3,363 ft), with a surface elevation about 28 m (92 ft), but it fluctuates considerably, rising at the present time due to increased rainfall in the intake areas.

Its marginal areas are marked by very considerable petroleum reserves, those around Baku (Azerbaijan) being amongst the oldest to be exploited. Newer discoveries mark the borders of Kazakhstan. Another economic product is the caviar, obtained from the sturgeon caught in the Volga estuaries, and also from Iranian sources.

On the eastern side (Turkmenistan) is a wide shallow embayment, the salty Zalif Kara-Bogaz Göl, some 160 km wide, separated from the main body of the Caspian by a long spit, but connected at the N end by a narrow channel. This Kara-Bogaz Gulf has long been famous for its remarkable salt accumulations.

2. *Aral Sea*, is situated partly in Kazakhstan, partly in Uzbekistan, and once placed as the second largest water body in Asia, formerly fourth largest in the world. In Roman times, it was known as *Oxianus Lacus*. Its area was 67,000 km² (26,000 square miles). It was 450 km (280 miles) long. However, during the mid-twentieth century, its intake waters were severely curtailed by irrigation dams on the Syr Darya and Amu Darya and also by persistent droughts. As a result, its volume was reduced by about 90% by the beginning of the twenty-first century. A large fishing industry was destroyed.

Discoveries in the early twentieth century by Ellsworth Huntington the American explorer showed that the Amu Darya formerly flowed into the Caspian, but climate changes and drifting sands from the Kyzylkum Desert blocked its Caspian channel and established the Aral Sea connection, now interrupted once more.

3. *Kaludinskoye Ozero*, located 300 km SW of Novosibirsk, in the wide Kulundinskaya Steppe. Covering about 728 km² (280 square miles), it has no outlet and is quite salty. It is about 190 m above sea level.
4. *Chany Ozero*, in the NW Novosibirsk Oblast, located 250 km E of Omsk and 20 km S of Chany station on the Trans-Siberian Railway. It occupies a slight depression in the wide Barabinskaya Steppe. The lake is about 2,500 km² (965 square miles), at an elevation of about 180 m. It is fed by streams from swampy arms to the east but has no outlet.

Structural depressions

1. *Lake Baykal (Baikal)*, situated in the Buryat Republic of southern Siberia, covers 31,500 km² (12,162 square miles), being 635 km (395 miles) in length and has a remarkable depth of 1,620 m (5,313 ft), with a 31,500 km³ capacity, which makes it the largest freshwater lake in Asia, sixth largest in the world, and the deepest in the world. Its intake flow is by the Berguzin R. and Selenga R. on the east side and the Upper Angara from the N. Its outlet is in the S.W. to the Angara proper (on Upper Tunguska). It was discovered by Russian explorers in 1643. The lake is frozen in winter. Its biota, including seals related to Arctic and Caspian forms, is marked by many Arctic marine fauna, which suggest marine connections at least in the Miocene or even earlier. Climatologically, Lake Baykal plays an important moderating effect on the otherwise extreme continentality of the region. Deep drilling in recent years has disclosed a long history of climate changes in the lake and its environments.
2. *Hövsgöl Nuur* (göl = lake in Azeri language; nuur = lake in Mongolian) is located in northern Mongolia about 250 km WSW of Lake Baykal, to the S of the Sayan Range. Hövsgöl (also known as Kosogol) covers 2,620 km² (1,010 square miles) and is about 1,713 m (5,620 ft) above sea level. Mountains to the N reach 3,492 m, and the E 2,396 m (5,620 ft). It has an outlet in the S by the Egiyum Gol which connects to an extensive network to the east.

Intermontane basins

1. *Lake Balkhash* (Ozero) is a partially salt lake in eastern Kazakhstan, fed by the Ili R. and others in the east, but lacking any outlet. Its southwestern part is largely swamp. Near the mouth of the Ili R., it is almost fresh, salinity increasing toward the E where there is a modest salt industry. There is also commercial fishing. It covers 19,140 km² (7,115 square miles) and measures 605 km (376 miles). Remarkably shallow, 26 m (85 ft), its capacity is only 18,200 km³.

It is hemmed in to the N and NW by the Kazakh Hills but appears to have been progressively constricted by growth of the Sary-Ishik-Otran Desert with its alluvial fans and dunes emanating from the Djungurskiy Alatau Mountains that mark the border of western China. The east end of the lake shows connections with a string of smaller lakes including L. Alakol (see below).

2. *Khanka Ozero* (Hsing-kai Hu, in Chinese) is situated across the China-Russia border, some 200 km N of Vladivostok. It is in the Primorski Krai of Russia (about three quarters). Covering about 4,400 km² (1,700 square miles), it is 88 km long (55 miles), and 10 m (33 ft) deep. Its waters are fresh, with an outlet on the E into the Ussuri R, which forms the international boundary, flowing N to join the Amur near Khabarovsk.

3. *Lop Nor* (Lo Pu No Erh, in Chinese) is a shallow salt lake, marshy in part, at the E end of the Tarim Basin of western China (Sinkiang Uighur). It is about 3,500 km² (1,350 square miles) and is fed by the Tarim River, the course of which has changed somewhat through history, following the N. border of the Taklimakan Desert (Shamo). The lake is normally about 60 km long but, in wet cycles has expanded to 400 km. This was the former "North Route" of the famous "Silk Road" from China to the West, the routes matching the climate cycle.
4. *Uvs Nuur*, a lake in NW Mongolia at the foot of the Tannu-Ola Range that borders Siberia. It is 3,350 km² (1,295 square miles) and about 2,500 m above sea level. Marked by endorheic drainage, it is clustered with some smaller interconnected lakes, Har-Uus Nuur, Har Nuur, Döröö Nuur, and Hyargas Nuur (1,480 km²), all lying N of the Altai Mts.
5. *Alakol Ozero*, situated in Kazakhstan, E of Lake Balkhash in a chain of small lakes (including Sasykkol). It covers 2,650 km² (1,025 square miles). Elevation is about 1,700 m (5,575 ft). It is bounded to the S by the Dzhungarskiy Alatau Range and to the N by the Tarbagatai Range.
6. *Ebinur* (Ai-pi Hu in Chinese), a salt lake in western China near the border of Kazakhstan. It is situated at the W end of the Junggar Pendi (Basin) and appears to be the SE member of a chain of lakes starting with L. Balkhash, separated by a narrow pass in the Djungarian Alatau known as the Djungarian Gate. It is bounded on the S by the Borohoro Shan, a branch of the Tien Shan, which provides meltwater streams that feed the lake in summer. Its areal dimensions vary seasonally, up to 1,420 km² (550 square miles), at less than 200 m above sea level.
7. *Qinghi Hu*, a salt lake in an endorheic depression N of the Qinghi Nanshan range, and E of the Qaidam Basin. It is about 100 km long and covers 4,220 km² (1,625 square miles). Its depth is 38 m (125 ft) at an elevation of 3,205 m (10,515 ft). It is fed by streams from the NW (Datung Shan), notably the Buh He.
8. *Bosten Hu*, about 3,000 km² (1,160 square miles) and situated in a trough between two branches of the Tien Shan, to the N of the Tarim Basin. It has no outlet, but is fed by streams from all sides, notably the Kaidu He from the west.
2. *Lake Urmia* (or Urumiyeh; Shahi in Persian; also *Lake Rezaïyeh*; or *Matianus*, in ancient literature). Located in NW Iran, it is a shallow, saline lake, E of Rezaïyeh and W of Tabriz. Its area is about 4,700 km² (1,815 square miles), about 145 km (90 miles) long, and about 15 m (50 ft) deep. Shahi Island is in the middle. The lake is about 1,297 m (4,353 ft) above sea level. It is fed by the Talkheh R. from the NE and the Elborz Mts., and by the Zarineh R. from the SW, and the Zagros Mts. It has no outlet and is thus hypersaline (about 23% salt), but it varies greatly with the seasons. It cannot support normal lacustrine life. Thanks to a deep boring, it has been studied geologically by a German team.
3. *Lake Van* (*Van Gölü*, the latter meaning salt lake in Turkish; *Thospitis* in ancient times) is situated in eastern Turkey in the Armenian "knot" between the Taurus Mts to the S and Süphon Dag (4,058 m) to the N. It has an outlet in the W to the Bitlis R, a tributary of the Tigris, with several small feeders from the E and S. The water is brackish. Formerly, it fed into the Euphrates, but the outlet was blocked by the lavas of a volcano. It covers 3,760 km² (1,919 square miles), about 128 km (80 miles) long, and about 25 m (82 ft) deep. Its elevation is 1,720 m (5,643 ft).

Fluvial floodplain

1. *Tonlé Sap* (Grand Lac, in French) is a quite remarkable water body, in western Cambodia, that is linked by a reversible channel to the Mekong River which runs to the W, filling the lake when the Mekong is in flood, but to the E at other times. Its outlet is at Phnompenh. At its maximum state, it covers 6,475 km² (2,500 square miles). The celebrated Buddhist temples of Angkor (of the Khmer people) are at the W end of the lake, but were inundated periodically during the Middle Ages and deeply buried by 3–7 m in sediment.

Reservoirs and man-made lakes

As may be expected for a continent with broad expanses of desert and vast numbers of small endorheic drainage systems, Asia possesses an extraordinary number of reservoirs and other man-made water bodies. Ancient civilizations led the way in China, India, and the Middle East.

In China, major engineering work was applied to the Yellow River (Hwang Ho) which is 4,671 km (2,903 miles) in length. It normally debouches into the Gulf of Chihli in the Yellow Sea (Bo Hai), but has been periodically shifted to a system of lakes and canals to join up with the Yantze Kiang at Nanjing. The most recent engineering undertaking has been the Three Gorges dam which is probably the world's largest.

In India, in the time of the British "Raj," there were extensive modifications to the upper tributaries of the Indus, mainly for irrigation purposes. Here, the earliest

Orogenic trough

1. *Issyk Kul* (köl), a brackish lake in N.W. Kyrgyzstan, separated from Kazakhstan on the N by the Kungei Alatau and from Western China in the S. by the Tien Shan Mts. It covers 6,200 km² (2,394 square miles) at an elevation of 1,609 m (5,279 ft). It measures 185 km (115 miles) in length and 98 km (38 miles) across. Depth is 702 m (2,303 ft). From time to time, it receives water from the Chu R. at the W end. It has no outlet and sits in a rain shadow of over 6,000 m mountains.

operations were about 5,000 years ago by the Harrapan people to provide urban supplies to the city of Mohenjodaro.

In modern Iraq (ancient Babylon, Assyria, Sumaria, etc.), the Tigris (1,890 km, 1,180 miles long) and the Euphrates (3,597 km, 2,235 miles) run more or less parallel, but in ancient times, its lower course lay farther to the west and large lakes were created. Both rivers have been dammed in the Turkish area and long reservoirs created.

In Yemen, there was a famous dam that collapsed during an earthquake in the fifth century AD, which led to great social distress. In modern Israel, extensive use of the Jordan water and salt exploitation of the Dead Sea have also created problems.

AUSTRALIA, CLIMATE AND LAKES

H. A. Bridgman¹, Brian V. Timms²

¹Department of Geography, University of New England, Newcastle, NSW, Australia

²Department of Science and Information Technology, School of Environmental and Life Sciences, University of Newcastle, Callaghan, NSW, Australia

Introduction

Australia is an aged, flat continent. With the exception of the Eastern Highlands, especially in North Queensland and in areas of the Snowy Mountains in New South Wales and Victoria, there is little terrain. Lakes tend to be shallow and often ephemeral. Two well-known examples are Lake Eyre, in South Australia, and Lake George, outside Canberra ([Figure 1](#)). Lake Eyre is famous for its spectacular wildlife explosions during the rare occasions when standing water is available. Lake George is well known for its paleoclimatic and paleolimnology information (Timms, [1992](#)). These and many other lakes will fill under high rainfall and runoff conditions. Except for coastal lakes, total water evaporation often occurs in drought conditions.

General climatic features

The Australian continent is mainly located under the descending branch of the tropical (Hadley) circulation cell. Subsidence creating dry warm air encourages dry conditions at the surface. More than two-thirds of the continent receives less than 500 mm per year of rainfall. The age and terrain of Australia provide limited influences on atmospheric circulation (Bridgman, [1987](#), [1998](#); Hobbs, [1998](#)). [Figure 2a](#) and [b](#) shows a simplified synoptic climatology for Australian winter and summer conditions. Autumn and spring are transition seasons. In winter

([Figure 2a](#)), the northern two-thirds of the continent is under the influence of the southeast trade winds. This is the dry season of the year for the north, with the only major rainfall from orographic process on the Eastern Highlands in coastal Queensland. The geographical center of the anticyclonic movement is from 30°S to 33°S. Farther south, frontal and cyclonic (hurricane) activity associated with the circumpolar westerlies dominates, creating the winter season of maximum rainfall in the Perth area, southeast South Australia, Victoria, Tasmania, and southern New South Wales. Cold fronts linked to lows located south of the Great Australian Bight often extend north of 30°S, but rainfall is sporadic from these systems.

In contrast, summer circulation is more complex ([Figure 2b](#)). The center of anticyclonic movements shifts south to between 38° and 40°. This change allows onshore circulation patterns in the southern half of the continent. Sea breezes and mesoscale frontal systems occur regularly in coastal zones (Sturman and Tapper, [1996](#)), with the latter bringing moist air onshore. A combination of orographic and convective processes creates a summertime maximum in rainfall in New South Wales and Queensland. In the north, the Australian “monsoon” is usually active. The two major heat lows (Pilbara in Western Australia; Cloncurry in Queensland) are instrumental in encouraging the Intertropical Convergence Zone to move into the northern part of Australia. Moist, hot northwesterly winds follow, creating major rainfall between late November and early March. [Figure 3](#) provides a contrasting summary of rainfall and climatic zones for the Australian continent.

Late summer to early autumn is also the tropical cyclone season (Bridgman, [1998](#)). On average, eight to ten cyclones can form in the warm seas adjacent to both the northwest and northeast coasts of Australia. About half reach landfall, often after recurving in southerly direction from initial westerly tracks. When they move inland, the associated heavy rainfall can result in severe flooding, which carries to southern parts of the continent through swollen river systems. During these periods, the lakes are normally full of water, and wildlife moves inland from the coast.

Climatic variations

Variations to this general climatic pattern bring the extreme periods to Australian climate which are well known to the population. Particularly significant are extended periods of drought, high temperatures, and high variability of rainfall. It is not usual for a long period of drought to be broken by a period of heavy rainfall, replacing dry landscapes with floodwaters.

Much of these variations in eastern Australia can be attributed to changes in pressure between the western and eastern Pacific. This difference in pressure is calculated on a daily or monthly basis through the Southern Oscillation Index (SOI) (see Hobbs, [1998](#); Sturman and Tapper, [1996](#) for useful summaries). There is a significant

Australia, Climate and Lakes, Figure 1 Map of Australia showing the larger relief features and the location of lakes described in the text (Drawn by Olivier Rey-Lescure, University of Newcastle, NSW, Australia).

correlation between SOI, and variations in diurnal temperature range, precipitation, and cloud cover over much of eastern and northern Australia (Bridgman, 1998). When the SOI is average or positive (La Niña), convective conditions leading to normal to high summer and autumn rainfall in northern and eastern Australia prevail. During these times, river flow is high and most lakes are full of water. When the SOI is negative, the pressure variations between the eastern and western Pacific reverse, creating an El Niño situation. Drought conditions in much of eastern Australia can prevail, depending on the strength and duration of the El Niño event, and many lakes dry up.

Hobbs (1998) emphasizes that the Southern Oscillation has an imperfect relationship with Australian rainfall, indicating that other factors are important. For example, rainfall amounts are strongly linked to sea surface temperature (SST), which can vary for other reasons besides the SO. While warm SSTs can lead to heavy rainfall, and cold SSTs the opposite, the impacts can be very complex

and result in a mix of wet and dry areas depending on geographical location.

Another important feature that influences Australian climate is the circumpolar westerly circulation around Antarctica (Karoly et al., 1998). Waves in this circulation pattern in the mid- to upper troposphere are divided into two types: those that are relatively stationary over long periods of time (Waves 1, 2, and 3) and those that are smaller and are transient over time (Waves 4, 5, and 6). Waves 1 and 3 affect the interaction in airflow from Antarctica to Australia the most, especially over the western half of the continent. Small shifts in the location of these stationary waves from season to season can have major influences on rainfall and temperature variations over Australia.

Lakes in Australia

On a world scale, Australia has relatively few lakes, which is not surprising given that 39% of the continent is arid and another 39% semi-arid. Nevertheless, maps show many

Australia, Climate and Lakes, Figure 2 (Continued)

dry lakes in the interior, and parts of the well-watered southeast and far north are dotted with numerous, mainly small bodies of water. The physical characteristics of many Australian lakes have been reviewed by Timms (1992). The aim here is to highlight just a few examples of various geomorphic types with respect to present and past climatic variations across the country.

The few tectonic lakes can be represented by Lake Eyre and Lake George, both large and ephemeral. Volcanic lakes are common enough in western Victoria; the permanent and deep Lake Keilambete in a crater contains a record of past climatic variations, while the nearby shallow Lake Corangamite in a lava field reflects more

proximate rainfall variations. Lynch's Crater in North Queensland provides a climatic record going back 120,000 years BP. Lakes due to past glacial activity abound in Tasmania, and there are a few on the mainland as well. All are permanent and reflect a different climatic pattern to that typical of Australia, as will be seen from Blue Lake and Lake St. Clair. Lake Selina, in western Tasmania, has yielded a 160,000-year record of paleoclimates, similar to the Lynch's Crater record, but with different vegetation responses due to the two being in contrasting climatic types. Lakes formed by wind action are common both in the inland and along parts of the coastline. They are subject to very different climatic

Australia, Climate and Lakes, Figure 2 Simplified synoptic climatology for Australian (a) winter and (b) summer conditions, showing large-scale circulation features (After Bridgman, 1987) (Drawn by Olivier Rey-Lescure, University of Newcastle, NSW, Australia).

regimes as will be seen by examining the inland Salinaland Lakes of Western Australia, Lake Wyara in southwestern Queensland, and the coastal dune Lake Boemijin on southeastern Queensland. Finally, coastal lakes containing marine water abound particularly in southeastern Australia. Studies on the Gippsland Lakes show them to be very different from other types of Australian lakes. They occur also in Southwestern Australia on a rather smaller scale.

Most of these lakes are discussed below (see Figure 1 for locations), but there are separate entries for Lake Eyre, the Gippsland Lakes, and the Salinaland Lakes.

LAKE GEORGE: A tectonic lake located near Canberra in the southeast, Lake George typifies many Australian lakes in that it is shallow and intermittent (Timms, 1992). It lies in a graben against the Cullarin Horst, easily revealing its tectonic origin. When “full,” it is 155 km² in area and 4.6 m deep, but 25,000 years ago, it was much bigger and 37 m deep. A series of raised beaches trace its demise from a permanent lake in a cooler climate with lower evaporation during the last glaciation to its present state (Coventry, 1976). During the last 180 years, its fluctuations in water level have not been dramatic as those in Lake Eyre because it is located

Australia, Climate and Lakes, Figure 3 Summary of rainfall and climatic zones for the Australian continent (After Bridgman, 1987) (Drawn by Olivier Rey-Lescure, University of Newcastle, NSW, Australia).

in a more benign climate with lower evaporation and more reliable inputs (Jennings, 1981). Nevertheless, there have been dry periods (e.g., 1940; 2001) and “full periods” (e.g., 1960), but these hardly correspond with ENSO climatic variations as in inland lakes further north.

LAKE KEILAMBETE: A volcanic lake (maar) located on the volcanic plain of western Victoria, Lake Keilambete is 277 ha in area, 11 m deep, and contained in a steep-sided, flat-floored crater (Timms, 1992). Presently, its waters are more than twice as saline as the sea. However, this has not always been the case over its 10,000-year history. Its isolation from regional water tables and “rain gauge” like characteristics bestows a giant evaporimeter status upon it, which is useful in detecting past climatic events in its sediments (Chivas et al., 1986; Jones et al., 1998). For example, the climate was drier, as indicated by higher lake salinities (determined by three independent methods) 2,000–3,000 YBP, and wetter *ca* 4,500–8,000 YBP.

LAKE CORANGAMITE: Located near Lake Keilambete, this lake lies in depressions between lava flows and is much bigger (25,160 ha) but is rather shallow (<5 m) (Timms, 1992). It is the largest permanent saline lake in Australia and was even larger (seven times) during the Holocene. This change was not caused by climatic

variations but due to natural changes in drainage patterns (Currey, 1964). Over the last century, salinity fluctuated widely but has been increasing in recent decades from ~20 to ~60 g/L. Until the 1960s, these fluctuations were largely associated with short-term climatic fluctuations, but the diversion of a major inlet at that time now starves the lake of water. The fauna has changed and the value of the lake for waterfowl, which use it for breeding, feeding, and as a drought refuge, has largely been lost (Williams, 1995). The situation is still reversible.

LYNCH’S CRATER: Now a swamp, Lynch’s Crater is a much older volcanic feature in northeast Queensland. A core tracing its history over 120,000 years (Figure 4) reveals major changes in the surrounding vegetation and hence climate in the eastern wet tropics of Australia (Kershaw, 1978). Tropical complex rainforest dominated during the most recent 10,000 years and again pre-79,000 YBP. In between times, drier vegetation types of Araucarian forest (79,000–26,000 YBP) and sclerophyll woodland (26,000–10,000 YBP) surrounded the crater (see Figure 4). These changes have been associated specifically with rainfall fluctuations, rather than with more general climatic variations, though the correlation between the two, as seen in deep-sea cores, is excellent.

Australia, Climate and Lakes, Figure 4 Vegetation cover and mean annual rainfall for the past 123,000 years from pollen in the sediments of Lynch's Crater, northern Queensland (17°S), indicating major changes in rainfall over time (Adapted from Kershaw, 1978), compared to vegetation cover over a time similar in the sediments of Lake Selina, Tasmania (41.5°S) (Colhoun et al., 1999). Both locations are in eastern Australia. Despite differences in latitude, there are broad similarities in moisture regimes reflected in vegetation changes (Drawn by Olivier Rey-Lescure, University of Newcastle, NSW, Australia).

Changes between wet and dry forests were abrupt, but during the period 38,000–26,000 YBP of the last glacial period, sclerophyllous vegetation slowly dominated, aided in part by more frequent burning by aboriginal people (Kershaw, 1976).

BLUE LAKE, KOSCIUSZKO: The Australian mainland has only four cirque lakes of glacial origin. Blue Lake

is the largest ($A = 14.4$ ha) and deepest ($z_m = 28$ m) (Timms, 1992). It was formed initially in the Early Kosciuszko glaciation *ca* 59,300 years ago and reworked during three subsequent advances *ca* 32,000, 19,100, and 16,800 years ago during the Late Kosciuszko glaciation (Barrows et al., 2001). Blue Lake lies mainly in a rock basin, but thin ground moraine ridges at the lip

add to the depth of the lake. The basin of Blue Lake has *ca* 7 m of bottom deposits due to lacustrine sedimentation, and there are fluvial deltas restricted to nearshore. A submerged ridge of 3 m in the northern corner of the lake may mark a recessional moraine or is possibly a protalus rampart being built at the toe of a winter snow patch. The lake is permanent, has a stable water level, and contains extremely pure water of very low nutrient status, like few others in Australia. Also, it is one of only a few lakes in Australia to freeze over in winter and hence have a dimictic thermal regime (stratified in winter and summer), as opposed to most other lakes which are monomictic (stratify only in summer) (Raine, 1982).

LAKE ST. CLAIR: A piedmont glacial lake in the highlands of Tasmania, Lake St. Clair is the deepest natural lake in Australia at 165 m (Derbyshire, 1971). It is also comparatively large (2,818 ha). The location of the glacial trough is due to bedrock geometry and preglacial topography, but the detail is due to many glaciations. The Last Glaciation retreated in stages and concluded locally about 9,000 years ago (Kiernan, 1992). The lake occupies four rock basins, beyond the meeting of four valley glaciers. The deepest of these lies downstream of the entry point of two lateral glaciers that spilt over from the Central Plateau. There is also a fifth, much shallower basin in end moraine due partly to excavation by another lateral glacier. This impounding end moraine is less than 50 m deep, so excavation due to glacial action is great by Australian standards. Like other glacial lakes in the temperate, moist climate of Tasmania, Lake St. Clair is permanent and has good quality clear waters, with little variation in water levels.

LAKE SELINA: A small lake in a Pleistocene-glaciated valley in western Tasmania, Lake Selina escaped the most recent Wisconsin glaciation. A 397-cm core from its sediments reveals a climatic history for the area dating back 160,000 years (Colhoun et al., 1999) shown in Figure 4. For the last 14,000 years, the area has been clothed in cool temperate rainforest dominated by *Nothofagus cunninghamii* (Southern Beech). During the Wisconsin glaciation, the surrounding vegetation was of alpine grassland and heathland grading to shrubs at *ca* 60,000 YBP. Going back another 55,000 years, the surrounding vegetation oscillated between montane rainforest and shrub land and alpine/subalpine heathland and herbland. Beyond 115,000 YBP, the pollen deposits tell of cool temperate rainforest like that of the present. These vegetation changes point to climatic fluctuations between the present cool, wet temperate conditions to periods when average temperatures were $> 3.5^{\circ}\text{C}$ (and up to 6.5°C in mountains nearby) cooler and even a time when temperatures may have been warmer.

LAKE WYARA: This saline lake lies in southwest Queensland adjacent to the Paroo River into which it occasionally overflows (Timms, 1998). Generally, it fills and dries episodically and is very much influenced by rainfall patterns associated with atmospheric circulation patterns in the Southern Hemisphere as measured by the Southern

Oscillation Index (Karoly et al., 1998). During strongly negative SOIs, there is below average rainfall in northern and central Australia and Lake Wyara dries (El Niño years), while conversely during strongly positive SOIs, rainfall exceeds the average and Lake Wyara fills, sometimes to overflowing its generally closed catchment (La Niña years). At such times, it is 3,400 ha in area, nearly 7 m deep, and almost fresh. More normally, it is 2,500–3,000 ha in area, 1–2 m deep, and hyposaline-mesosaline. Its large catchment and size make it the best barometer of rainfall variation among the lakes of the Paroo region. The correlation between the SOI and full and dry periods over the last 110 years is highly significant ($r = 0.622$, $n = 34$) (Timms, 1998).

Lake Wyara lies at the edge of the Paroo floodplain and on a tertiary fault. The relative contribution to the depth of its basin by faulting reduced deposition at the edge of the floodplain, and deflation is unknown. Deflation is probably the most important, but the eastern shore lacks Holocene lunette dunes that are present downwind of many other local lakes which tend to fill and dry seasonally. However, a subdued much older lunette dune is present, indicating its greater age and response to different climatic conditions in the past.

LAKE BOEMINJIN: The east coast is fringed in many places with siliceous dunes which are particularly expansive in southeast Queensland. Some offshore islands are entirely of such sands, including the world's largest sand island, Fraser Island, 200 km north of Brisbane. Given the ready porosity of these sands, it is surprising Fraser Island is dotted with lakes well above sea level. These lakes, of which Lake Boemjin (or Boemingen) is a large example, are perched above the widespread water table and owe their origin to special processes (Bayly, 1964).

Lake Boemjin ($A = 297$ ha, depth < 5 m) lies in a deflation basin 74 m above sea level. The surrounding dunes are well vegetated, and the climate is subtropical with no dry season. Fine organic material from the leaf litter is washed into the hollow, percolates downwards, and, by podzolization, forms a B-horizon of relatively impermeable cemented sand. A perched water table results. Other lakes in the area are of similar origin, but instead of lying in a simple deflation hollow, the hollow is more complex (e.g., Lake Bowarrady) or lies within a parabolic dune (Lake Poona) or is due more to damming than deflation (e.g., Brown Lake on Stradbroke Is) (Timms, 1992).

Whatever their geomorphic origin, these lake waters are humic due to a large dissolved organic matter fraction. This imparts unique properties to the lake associated mainly with its low pH (*ca* 4–5), abundance of bacteria consuming the dissolved organic matter, and a simplified food chain based on unusual food energy source. Variants of perching and geomorphic origin result in slightly different limnological conditions in coastal dune lakes along the east coast (Timms, 1992), but all owe their presence to some degree to climatic conditions suitable for podzolization of siliceous sands.

Australian lakes are different in many respects to those on other continents or large islands due largely to the great age of landscapes and the limited extent of Pleistocene glaciations. Most lakes are intermittent and many are saline. Lakes due to glacial action are relatively uncommon, except in Tasmania, while wind action is important in the inland and in coastal areas. Also, mainly in coastal southeastern and smaller ones in southwestern Australia, many lakes are due to Holocene marine oscillations. The contrasting climates in northern and southern Australia impose differing hydrological conditions and vegetation in the catchments, but, as [Figure 4](#) shows, there are broad similarities in the rainfall regime over geological time. The sediment record tells a very complex story of fluctuating climates, varying rainfall patterns, and change in lake levels during the Pleistocene.

AUSTRALIA, COASTAL PALEOLAKES OF "SWANLAND"

Rhodes W. Fairbridge (Deceased), Lars Bengtsson¹
¹Department of Water Resources Engineering, Lund University, Lund, Sweden

Definition

Very strong seasonality is a feature of Southwestern Australia, as well as parts of South Australia and some other areas of the continent. This means that many large rivers tend to be greatly reduced in discharge during dry seasons when rainfall in their interior basins may be as little as zero. The southwestern and southern coasts are subject to almost continued swells set up by storms in the Southern Ocean. As a result, regardless of local meteorological systems, there is almost constant heavy wave action from the southwest. On the west coast, the beach sands migrate from south to north, and on the south coast, they migrate from west to east. In this way, even major estuaries are seasonally blocked and become lakes.

In addition, during dry seasons, with onshore winds aided by the diurnal sea breeze, major dune accumulations are observed. Furthermore, during the Holocene, major climate cycles introduce wetter and dryer intervals at 1,500–3,000-year periodicities. The geochemistry of the sands is also a significant factor. In the south, the beach sands are prominently derived from granite-gneiss weathering, but on the west coast, north of about 35°N, the sands are markedly calcareous due to a mix of debris from large foraminifera, corals, and crushed bivalves. When blown up into dunes, these sands are loose, but after a few wet cycles, they begin to dissolve and CaCO₃

cement begins to lithify the dunes to a rock known as eolianite. After a few millennia, this rock is still quite friable, but after 10, 000 years or so, it becomes a resistant limestone (widely favored for foundation stones by home builders). In South Australia (S.E. of the Murray entrance), the entire Quaternary, thanks to a slight crustal uplift, is represented by about 18 interglacial intervals of eolianite building (Sprigg, 1979). The Murray River is Australia's largest drainage system, yet from time to time it has been blocked by littoral drift and large coastal lakes created, notably Lake Alexandrina. Early colonists' dreams of using the Murray for a regional port were dashed by this seasonality.

In Western Australia, the Quaternary eolianites reach elevations of more than 300 m in the region of Shark Bay and are a major feature of the coastline for over 1,000 km. In the coastal plain of the southwest, their highest elevations are less than 100 m, forming irregular hills up to 10 km inland. During the low sea-level phases of the Pleistocene, the main river valleys were cut down by the increased discharge (heavy precipitation in the coastal ranges) and channels cut through the eolianite ridges. With the interglacial rise of sea level, large paleolakes were created. After reaching their maxima, outlet channels were formed, and all the major examples are now, at least partly, tidal estuaries. They are characterized by large inland water bodies connected to the ocean by narrow channels. Examples include:

- (a) Melville Water and Perth Water, fed by the Swan and Canning rivers with their combined exit channel at Fremantle. Highly fossiliferous spits (with marine fossils) mark the trace of the last interglacial marine inundation, when sea level reached at least 5 m above present (see map in Jutson, 1934, from Somerville (1919); for "elevation," read "emergence," i.e., a eustatic factor). Today, the salinity is only slightly brackish at times. An appreciation of the coastal limestone may be found in an admirable ecological and historical volume on the Perth area by George Seddon (1970). The eustatic nature of the emerged ridges was first recognized by Fairbridge (1954), but the wind-blown nature of the eolianites ("Coastal Limestone") was recognized by the earliest voyagers and their karstic features correctly explained by Charles Darwin (1845).
- (b) Peel Inlet, with its narrow outlet at Mandurah and fed from the plateau by Murray Williams and the Serpentine. There is some tidal exchange, so the waters are rather brackish.

Along the coast, south of Peel inlet, are three elongate water bodies of totally distinct origin. They are entirely of Holocene climatic-eustatic causes, being an echelon (Lakes Preston and Clifton) and separated by major beach ridges built up by episodes of strong southwesterly storms. These two, Preston and Clifton (respectively 28 and 20 km long but only 1 km across), are completely isolated from the ocean, but a third one, the Leschenault Inlet, is open at its south end near Bunbury which is influenced by intake from the Collie River. All are strongly influenced by the carbonate sands that dominate the beaches and in places are marked by distinctive shell beds.

On the south coast, the impact of the Antarctic swells tends to build beaches toward the east, and the eolianite topography controls much of the coastline. Seasonal closures of the lower, estuarine courses of the major rivers create ephemeral lakes. Deep River (which heads in a small lake 70 km inland) and the Frankland River both debouch into a wide embayment determined by eolianite hills resting on Precambrian prominences. The same setting determines the remarkable form of King George Sound (with the port of Albany), which provided HMS Beagle a safe haven and Charles Darwin an opportunity to study the eolianite. Much later, Fairbridge and Teichert (1953) were able to recognize multiple generations in it, separated by paleosols (with evidence of cool, wet cycles) and even multiple oscillations of sea level (with marine brands, some from the last interglacial); innumerable small paleolakes conditions are evidenced by localized piping and karst phenomena.

B

BAIKAL, LAKE

Laurent Touchart

Department of Geography, UMR 6042 CNRS, University of Limoges, Limoges, France

Introduction

Lake Baikal contains one fifth of the freshwater resources of the world, i.e., according to the recent unpublished studies of Alekseev et al. (2002), 23,615 km³. This Russian lake, the deepest in the world (1,637 m), is located in southeastern Siberia. It is 636 km long, from 51° 27'N to 55° 46'N, and covers an area of 31,722 km². Lake Baikal, which appeared 25 million years ago, is the oldest lake on Earth. Owing to its large size and great age, speciation was responsible for a very rich endemism which is very vulnerable to pollution.

One of the most famous lakes in the history of limnology

Russians conquered the region of Lake Baikal in the seventeenth century. Some learned travellers, such as ambassador Spafari, and exiles, such as the protopope Avvakum, described the lake. In the eighteenth century, soldiers and sailors, such as Bering, needed a map, since a navy was created on Lake Baikal. During the naturalist expedition of Pallas and Georgi in 1775, Pushkarev surveyed the topography of the lake and its surroundings for the first time. Lake Baikal entered the scientific world in the 1860s, when numerous Polish revolutionaries were deported to the region of Irkutsk. Some of them were scientists and studied the lake. Dybowsky, a specialist in gammarids, was the first Baikalian biologist and Chersky was the first geologist. The construction of the Trans-Siberian Railway, which reached Irkutsk in 1898, favoured human migrations and increased the need for scientific

studies for the safety of the ferries crossing the lake. The Trans-Siberian Railway had its own scientific journal, in which Obruchev, named “the father of Siberian geology,” wrote many articles about the faults of the region and the origin of Lake Baikal. After many expeditions from 1896 to 1902 and 274,369 soundings, Drizhenko produced the first bathymetric map of the lake.

In 1916, the Russian Academy of Sciences created the Commission for the Study of Lake Baikal, and, after the Revolution, in 1918, the new government founded the Biological Station of Bolshie Koty on the shore of the lake, and later, in 1928, the Limnological Station of Lake Baikal in Listvyanka. Vereshchagin, one of the world's most famous limnologists (Martinson, 1995), managed this station until 1942. Some well-known biologists of the postwar period, such as Kozhov, began their studies under the direction of Vereshchagin. After the war, the Baikalian Limnological Institute became one of the biggest in the world. Equipment was plentiful, for example laboratory ships. The Institute of Oceanology in Moscow regularly provided its submarine for the study of Lake Baikal. Since the collapse of the Soviet Union, there have been financial difficulties, but new collaborations have also emerged, particularly with American and Japanese researchers.

A very old rift lake

The Baikal tectonic valley is the central part of a complex rift zone located in Central Asia from the Mongolian Busingol and Khubsugul basins to the Tokko basin. The Baikal Rift Zone extends over 2,000 km above an anomalous mantle uplift. Compared with other rifts, particularly the East African Rift, the Baikal Rift Zone is the farthest from any ocean and from a major plate boundary. According to Molnar and Tapponier (1975) and Tapponier et al. (1982), the collision of the Indian Plate with and its penetration into the Eurasian Plate caused extrusion

M. Graffouillère, 2004, after Soviet topographic and bathymetric maps 1/200000 (courtesy L. Touchart) and GLOBE-NGDC

Baikal, Lake, Figure 1 Hypsometric and bathymetric digital elevation model (DEM) of Lake Baikal and its surroundings (Graffouillère, unpublished, after Soviet topographic and bathymetric maps 1:200,000 and GLOBE-NGDC).

tectonics, beginning in Indochina, then extending north like strike-slip faults in China and like a rift in the Baikal region. This passive theory is well accepted today by most geologists (Mats, 1993). Nevertheless, Zorin (1981) and Logatchev (1984) preferred the active theory, according to which the Baikal Rift Zone is an independent phenomenon induced by a local asthenospheric upwelling. In contrast with the East African Rift, volcanism is of secondary importance in the expansion of the Baikal Rift.

The lake itself lies in two deep tectonic basins separated by a submerged (Academic Ridge) and emerged (Olkhon Island, Svyatoi Nos Peninsula) uplift (Fig. 1). The southern basin from which rifting propagated is deeper and older than the northern basin. Oligocene sediments of the southern basin form the base of 7,000-m-thick deposits. The coastal landscape of Lake Baikal consists of rift shoulders and fault scarps. The most common aspect is a system of steep triangular facets with some intermediate steps (Ufimtsev, 1991). The basal slopes of the tectonic scarps form plunging cliffs.

The southern tectonic basin is made of two topographic depressions (Fairbridge, 1968), since the prodelta slope of the Selenga River cuts the basin in two parts (Fig. 2). Little

sediment is deposited from the central delta front, but fluvial material is rather channelled through a fault-controlled sublacustrine canyon named Kukui Gully towards the northeast (Karabanov and Fialkov, 1987). On the shoreline, fluvial deposits are redistributed and accumulate along bay head beaches, bay bars and spits.

Water temperature and mixing of the world's deepest lake

Lake Baikal is dimictic. After the homothermy of November, there appears a light slush (*shuga*), a mixture of internal ice consisting of anchor ice and melting snow, which turns into a dense and opaque sludge (*salo*) by the end of the month. By December, the drifting of the pancake ice (*blinchaty led*) causes the collision of the ice plates and rafts. The lake freezes over by the second half of December (this often happened at the beginning of the twentieth century, but seldom happens now) or, frequently for the last 20 years, by the first half of January. By February and March, the ice cover (*l'dina*) is 70 cm thick in the southern part to 130 cm thick in the northern basin, above a thermal inverse stratification of the water masses. By mid-April, the ice begins to thaw and break apart. By

Baikal, Lake, Figure 2 Hypsometric and bathymetric DEM of the delta of the Selenga River (Graffouillère, unpublished, after Soviet topographic and bathymetric maps 1:200,000).

May, the ice cover disappears from the southern basin and the second period of homothermy occurs. By June, only some floes float in the northern basin. The warm Siberian summer causes a direct stratification and, at the August maximum, the offshore surface layer reaches a temperature of 10°C (Fig. 3) above a 50- to 90-m-thick epilimnion. In the bays, the surface temperature sometimes exceeds 16°C .

This enormous water volume, slowly storing and redistributing energy, influences the climate of the land

around it and creates a limnoclimate which propagates along the Angara fluvial outlet. For example, in Irkutsk, 65 km from Lake Baikal, the annual thermal range is about 37°C , whereas the difference between August and February is about 45°C in the meteorological stations of south-eastern Siberia that are uninfluenced by the lake.

Dimixis of Lake Baikal is in fact largely complicated by its huge depth. During homothermy, free convection only occurs down to 250 or 300 m (Shimaraev et al., 1993). Only this surface layer is regularly mixed and passes in

Baikal, Lake, Figure 3 Map of the surface water temperature of Lake Baikal in August (After Akademiya Nauk SSSR, 1962; Touchart, 1994, 1998, 2003).

autumn and spring through the temperature at which surface water has its maximum density, i.e., 4°C. Below, water renewal is episodic. But since the temperature at water has its maximum density decreases with increasing depth, the base of the mixed layer may locally move to a depth at which its temperature reaches the temperature at which water has its maximum density (Killworth et al., 1996). The sinking plumes which result from the phenomenon of thermobaric instability allow the deep ventilation of Lake Baikal, so the concentration of dissolved oxygen reaches 9 mg l⁻¹ at the deepest points of the central basin.

Permanent wind-drift currents and autumnal waves

Numerous local currents certainly disturb the general circulation, but Lake Baikal is above all affected by long-lasting or permanent wind-drift currents (Fig. 4). During ice-free seasons, the 50-m surface layer has a cyclonic movement with maximum velocity in spring. It consists of two major cyclonic cells in the northern basin, one in the central depression and two in the southern basin with seasonal oscillation (Galazy, 1993). A minor cyclonic cell affects the Gulf of Barguzin and an anticyclonic one affects the Gulf of Larch Trees, which gives birth to the Angara outlet. The strait of Little Sea gives a linear direction to its current. During ice-cover seasons, the currents are minimum, but the same directions are preserved, except in the Gulf of Larch Trees.

Two dominant and regular winds are channelled through the rift valley. The Kultuk ("dead-end wind"), a very common southwest wind, blows especially in autumn. During anticyclonic conditions, the Verkhovik ("upper wind") is a frequent north or northeast wind which is stronger in the daytime. The very long fetch of these two winds causes dangerous waves which may reach a height of 6 m in the northern basin (Fig. 5). Transverse winds are less common and blow only locally over a shorter distance, but some of them are stronger. Very sudden autumnal waves are due to the Sarma, a transverse northwest stormy wind first channelled by the Sarma valley then by the strait of Olkhon Portal. In spring, the Barguzin, a transverse northeast wind, assaults the lake in powerful and impetuous gusts, breaking the ice of the central basin.

Chemistry, water quality and anthropogenic pollution

Because of the crystalline lithologic character of the drainage basin, the waters of Lake Baikal are poorly mineralized. The average natural amount of dissolved matter in the lake is 0.096 g l⁻¹ (Vereshchagin, 1949; Votintsev, 1961). Major ions (63.5 mg l⁻¹ HCO₃⁻, 15.2 mg l⁻¹ Ca²⁺, 5.2 mg l⁻¹ SO₄²⁻, 3.8 mg l⁻¹ Na⁺, 3.1 mg l⁻¹ Mg²⁺, 2.0 mg l⁻¹ K⁺) are uniformly distributed at all depths of the three basins throughout the year. The average concentration of silica increases with depth from 1.1 to 5.5 mg l⁻¹ and seasonally varies with the consumption of the diatoms in the upper layer.

Lake Baikal is oligotrophic. Nutrients are unequally distributed at different depths and in the three basins, with a maximum in the southern part of the lake. Also, their distribution varies throughout the year, with an annual maximum by February and a secondary maximum by June. The annual minimum occurs in August, coinciding with the maximum organic consumption and water temperature.

Significant anthropogenic pressure on Lake Baikal began in the 1950s with the construction of the Irkutsk hydroelectric power plant 60 km downstream of the Angara outlet. The resulting 80-cm rise of the average lake water level disturbed some littoral regions, increasing coastal erosion. The ensuing water turbidity destroyed some spawning areas. The most important development in the Baikal region was the construction of the Baikalsk Pulp and Paper Plant on the shore of the southern basin. This location took advantage of the large volume of pure water, the abundance of taiga raw material and the facilities for exporting the production via the Trans-Siberian Railway. This mill came into operation in 1966. Despite the construction of an efficient wastewater purification plant in 1969, which was modernized in the 1970s and recently transformed into a semi-closed circuit, the plant pollutes the lake. Incompletely treated discharges of wastewater contain PCBs and phenols. Lake sediments are contaminated over 3–14 km² around Baikalsk (Sukhodolov, 1996), and significant pollution affects the upper water layer as far as 15 km east of the paper mill (Fedorov et al., 1992).

Today, only 80,000 residents live along the 2,000-km shoreline of Lake Baikal, and the density in the drainage basin is less than five inhabitants per square kilometer. Anthropogenic pressure is concentrated in the southern basin, around the Baikalsk Pulp and Paper Plant and the mouth of the Selenga River, which brings pollutants from the Buryat towns, especially from Ulan-Ude.

Biogeographic characteristics of Lake Baikal: a very high degree of endemism

The very long isolation of Lake Baikal in connection with its large size has allowed the development of 1,085 plant species (including 679 diatoms) and 2,491 animal species, among which 80% of the pelagic organisms are endemic, comprising 87 unique genera and 11 exclusive families (Mazenova, 1995). These endemics have two origins. Some of them colonized the lake during successive periods when Baikal communicated with other regions, particularly with the Arctic Ocean. The second origin, the most frequent one, is due to evolution on the site itself (Kozhov, 1963; Kozhova and Izmet'eva, 1998).

The Baikal seal (*Phoca sibirica*), named *nerpa* by the Siberians, is supposed to have arrived by a very ancient migration, using the Yenisey and Angara river systems, and then to have evolved within the lake. Parasitological analogies with the arctic seal (*Phoca hispida*) confirmed that this freshwater mammalian is descended from a marine form. But genetic studies showed that its

Baikal, Lake, Figure 4 Map of the long-lasting wind-drift currents in the upper layer of Lake Baikal (After Sokolnikov, 1964; Mankovsky, 1964; Verbolov, 1993; Touchart, 1994, 1998, 2002).

colonization is very ancient, probably in the Miocene–Pliocene (Pastukhov, 1993). Owing to natural selection, the Baikal seal is distinct from its ancestors, with higher haemoglobin concentration in its blood, stronger claws and additional teeth, presumably because its dives are deeper, freshwater ice is harder and the fishes consumed are smaller than those in the Kara Sea.

The major source of food of the Baikal seal, the fat fish (*Comephorus baicalensis* and *Comephorus dybowskii*) of the lake, is a good example of indigenous endemic genera (Fig. 6). Named *golomianka* (“naked fish” because it is scaleless) by the Siberians, the fat fish is a half-transparent animal living in the deepwater masses. It is the only viviparous fish in which all females and numerous males die

Baikal, Lake, Figure 5 Map of the wave potential of Lake Baikal (Touchart, unpublished).

just after the birth of the larvae. It was probably a blind alley in natural evolution and speciation (Sideleva, 1982).

Protected natural areas

Lake Baikal and its surroundings have been protected since the decree passed in May 1960 on defence of the coastal forest and fishing supervision (Touchart, 1998).

The resolution of the Soviet Cabinet passed in June 1971 prohibited timber-floating on the tributaries and required the construction of wastewater purification plants in the drainage basin. In 1974, the Russian Nature Conservation Society created the “Commission for the Study and Public Awareness of the Questions about Nature Conservation of Lake Baikal,” which established special protected areas,

Baikal, Lake, Figure 6 The fat fish of Lake Baikal (After Sideleva, 1995).

especially so-called nature monuments. A resolution of the Communist Party Central Committee, passed in April 1987, created the protected zoning of the whole drainage basin (Vorob'yev and Martynov, 1989).

There are four statuses for special protected areas around Lake Baikal: 267 nature monuments (*pamiatniki prirody*), 26 preserved territories (*zakazniki*), two national parks (*natsionalnye parki*) and three nature reserve areas (*zapovedniki*). The most rigorous status is that of nature reserve, in which all activities except scientific research are prohibited (Gusev, 1986). The Barguzin Reserve (2,632 km²) was created in 1916, the Baikal Reserve (1,657 km²) in 1969 and the Baikal-Lena Reserve (5,600 km²) in 1989.

A certain continuity prevailed after the collapse of the Soviet Union. The federal law "On the protection of Lake Baikal," passed in May 1999 and often called "Baikal law" by the Siberians, has resulted in numerous government orders being issued, among which are the decree of September 2000 confirming the ecological zoning of the protected areas around Lake Baikal and the decree of January 2002 strengthening the protection of the Baikal seal and the Baikal salmon (*omul*).

Conclusion

Lake Baikal is a unique lake, with a rich biological endemism because of its age. Except in the southern basin, the water quality remains excellent for two reasons: protection is rigorous and the enormous volume of water, with a great diluting ability and a very long water renewal, allows it to be preserved in spite of the anthropogenic outflows. However, the threats are great and it is urgent to finish the construction of the completely closed water circuit of the paper mill or to cease the production of cellulose by a reconversion of the Baikalsk Pulp and Paper Plant. Since 1996, Lake Baikal has been on the UNESCO World Natural Heritage Site List.

BALATON LAKE IN HUNGARY

János Józsa¹, László Rákóczi², Tamás Krámer¹

¹Department of Hydraulic and Water Resources Engineering, Budapest University of Technology and Economics, Budapest, Hungary

²Environmental Protection and Water Management Research Centre Non-profit Ltd (VITUKI), Budapest, Hungary

Introduction

Lake Balaton is situated in the western part of Hungary. It is the largest lake in Central Europe with a 595 km² surface area. Its length is 78 km, the average width is

7.7 km and the average depth is 3.3 m. The maximum depth reaches to about 12 m in the *Strait of Tihany* separating the western and eastern bays of the lake. The total length of the shoreline is 235 km. The extent of the catchment area is 5,775 km².

The beginning and process of geologic development of Lake Balaton is a long-disputed problem. The different researchers are dealing with the history of the present lake bed itself, the catchment area or its wider surroundings. Accordingly, the estimations are varying from 12,000 years to 18,000–20,000 years.

Hydrographic description

The main tributary is the *Zala River*, flowing into the *Keszthely Bay* on the western part of the lake. Its drainage area occupies 45% of the total catchment area. The north-oriented [Figure 1](#) shows the creeks and artificial canals feeding the lake. The boundaries of their sub-catchments roughly indicate the extent of the former marshy areas intermittently inundated by the lake in the past before the regulation of the water level (1863). After two trials with different structures, the present concrete and steel weir at Siófok was inaugurated in 1947 through which the excess waters can be drained by the navigable *Sió canal* into the *River Danube*. The permitted range of water level variation was introduced in 1977, with a maximum of 100 cm above the “0” datum of the gauge. Due to the increasing recreational and environmental demands, the latter has been lifted to 110 cm in the mid-1990s.

Balaton Lake in Hungary, Figure 1 Lake Balaton and its catchment area.

Early observation of the lake water movements

VITUKI (*Research Institute for Water Resources* as named that time), responsible for the hydrological data collection, established a permanent measuring and research station at *Balatonszemes* in 1962 (Muszkalay, 1965). Besides continuously measuring the local wind direction and velocity, a network of 10 water level recorders has been established around the lake. Collection of wave data were started from a platform resting on piers driven into the lake bed, and the wind-driven water circulation was followed from an anchored vessel using marked buoys. The list and the locations of different hydrological observations are shown in Figure 2, again oriented to north.

The analysis of long-term wind records of the national meteorological station at *Siófok* showed that the prevailing wind directions are W, NW, and N. From the viewpoint of the denivelations of the water level (seiche), the frequency of SW winds, nearly parallel with the longitudinal axis of the lake, is rather low; however, its observed maximum is about 1.20 m. In the crosswise sense, the seiche is more frequent, and its maximum value is 0.40 m.

Due to its shallowness, the inner circulations of Lake Balaton are generated and maintained mainly by the mentioned movements of the water surface, i.e., by the highly transient wind activity over the lake. Expectedly, the highest flow velocities occur in the Strait of Tihany

(up to 1.40 m/s). In other parts of the lake, the flow velocities vary from 0.10 to 0.40 m/s, depending on their exposure to the wind and on the wind parameters. The hills covering the northern shore of the lake have a significant protective effect against the strongest winds; therefore, in the nearshore zones, significant currents can develop along them. Further results of shallowness are the large gyres, with diameters of several kilometers dividing the lake into big cells, their flow directions being opposite to their neighbors'. These main flow patterns were later generally supported by findings in hydraulic model tests and even by the results of recent numerical modeling.

Hydrodynamic research since the early 1980s

A complex international research project was carried out in *ILASA* (*International Institute of Applied Systems Analysis*), Austria, in the early 1980s with establishing measures to improve lake water quality as ultimate goal. The achievements of the projects (see van Straten and Somlyódy, 1986) were finally based on rather simplified hydrodynamics as limited field measurements could not validate sophisticated 2- and 3-D numerical flow models of that time. In the research projects of the late 1990s, in turn, a fruitful coupling of field measurements, theory, and computer modeling applying up-to-date instrumentation and numerical techniques could be performed

Balaton Lake in Hungary, Figure 2 Hydrometeorological observation network on lake Balaton (1964).

(Józsa et al., 1998). As the projects were carried out in several phases, the experience could be gradually utilized, and research tools as well as methodologies could be upgraded accordingly. Field measurements consisted of simultaneous, long-term, automated recording type of observation of the wind, flow, and turbidity at a number of representative lake sites. In most cases, the campaigns focused only on a particular part of the lake at once. In some phases, special emphasis was put on special issues, e.g., the wind speed variation along the fetch, water exchange at the interface zone of adjacent bays, or the circulation structure in nearshore regions. All the research projects were conducted in cooperation with the *Finnish Environment Institute*, whereas the up-to-date instrumentation was provided by *Aanderaa Instruments*, Norway. In fact, their wind station, propeller as well as Acoustic-Doppler type of current meters, and optical turbidity sensors proved very robust tools in most conditions (Tengberg et al., 2001). Of course, in order to apply them in the given shallow (typically from 1 to 4 m) conditions, special deploying techniques had to be developed.

In numerical model development, the mathematical description of the hydrodynamic and sediment transport processes were based on the traditional conservation laws applied to mass, volume, and momentum (see e.g., Simons, 1980). Starting from the general three-dimensional time-dependent approach, reasonable simplifications could be introduced due to the shallow water conditions. In order to describe the lake-wide water mass transport in most cases, the depth-integrated approach of the wind-driven circulation patterns proved sufficient. Model calibration and verification covered the proper tuning of wind, flow, and sediment transport models. It is important to underline that detailed analysis of the simultaneous wind data and thorough parameter calibration of the relationships resulted in a substantially improved estimation of the wind shear stress field over lakes. The essential of the approach, well known in boundary layer meteorology, but more or less ignored that far in lake circulations, laid in considering the development of a so-called *internal boundary layer (IBL)* downwind of an abrupt change in the surface roughness conditions (see Garratt, 1990, for an review), such as the one at the upwind lakeshore. The improved wind stress field could provide good fitting of calculated and measured flow patterns in a wide range of situations. The coupled measuring-modeling achievements could then provide significantly improved scientific support to decision making on, e.g., thin-layer dredging strategies in the most polluted western bays of the lake.

As to the bay-wide flow features, it was found that, in addition to the impact of uneven bathymetry (known as the origin of the so-called topographic gyres), they are influenced significantly by the non-uniformity of the wind stress field, as a combination of upwind topography (Józsa et al., 1990) as well as IBL development effects (Józsa et al., 2007), the latter playing the more

Balaton Lake in Hungary, Figure 3 Aerial photo of a bay showing the reed belt and the evolution of the brownish plume of a small effluent.

important role. In fact, a semi-analytical parameterization of that in numerical modeling provided an overall reasonable matching between measured and calculated horizontal circulation patterns. Considered in their overall complexity, flow conditions and their impact on mixing are well represented in Figure 3 by the plume of a small creek effluent to a bay, draining brownish water clear from suspended solids while flowing through the littoral reed belt. The plume serves here as a *Lagrangian* indicator of the lake dynamics, consisting of seiche- and circulation-induced advection, as well as wave- and turbulence-induced dispersion, all influencing the suspended solids transport and water quality of the lake, too.

Sediment dynamics

The mineral/chemical composition and the soil physical parameters of bottom sediment are important factors for both the investigation of biology and history of Lake Balaton. The repeated surveys of the lake bottom and the systematic core sampling programs made the estimation of the annual rate of silting possible. It was found that about 8,000 years ago, this was as low as 0.15 mm/year and increased to 0.80 mm/year in the last 1,000 years. The rate of silting up has significantly accelerated in the twentieth century and reached 7–10 mm/year (Szesztay, 1963).

Due to the shallowness of Lake Balaton, the wind-induced waves are reaching the bottom surface frequently. The uppermost 5–8 mm thick layer of the sediment is very loose and can easily be stirred up by wave effect, causing a suspended sediment concentration of about 300 mg/l in the 2–3 m deep water body. The suspended fine sediment

grains are transported with the velocity and in the direction of the water flow, often carrying chemicals from phosphorus to mercury attached to their surface to significant distances where they settle out. The transport process can be followed by placing several settling tubes on different points of the lake bed or suspended within the water body hanging from anchored buoys. The tubes have to be emptied from time to time and the mass of the settled suspended sediment grains determined. From these results, the flux of sediment transport for each tube can be calculated. The location of the highest flux indicates the main direction of suspended sediment transport.

Another way of sediment motion is *creeping* along the bottom in a 1–2-cm thick layer. This way of transport is much slower than in suspension; however, the mass of the moving bottom material is much higher. The estimation of their speed and direction is possible by using tracer methods. In Lake Balaton, having a great recreational value, *luminescent* tracers are used, wherever possible, instead of *radioactive* ones. In the sand, grain-size range artificial tracer grains (ground luminescent glass) were used; in case of silt, a pulverized Chromium-glass powder was produced. Both types of tracers were mixed with natural sand or silt grains respectively and placed to the lake bottom in one or more points. After longer windy periods, bottom samples were collected from the study area and the number of tracer grains counted in them. Furthermore the distance of sampling points from the start usually give enough information about the average velocity and direction of sediment movement. The latter is the more important in lake sediment transport studies because mostly the *direction* of the movement is decisive when the main *sediment scouring* and *accumulation* points or regions are to be determined.

Figure 2 indicates that the first tracer measurements were carried out in the *Keszthely Bay* in as early as 1964, the region heavily inclined to siltation. The field studies revealed the spreading characteristics of sediment brought into the lake by the *Zala River* and proved the existence of a broad stripe of sediment transport toward Keszthely along the wind-protected northern shore of the bay. Another long-term tracer measurement took place near *Balatonszemes* in 1963 where the bank material has been heavily eroded by the waves arriving from N-NW directions. The annual displacement of the luminescent glass grains ground to sand-size fractions demonstrated here the transport of the eroded bank material along the southern shoreline toward *Fonyód* with an average speed of 100–110 m/year. These findings in the early sixties significantly assisted the design of sediment dredging locations in the Keszthely Bay and that of the shoreline protection structures along the reaches mostly exposed to wave erosion.

As a major contribution to the above results, in the research projects of the late 1990s, turbidity data automatically collected simultaneously with wind and flow data were also analyzed. Turbidity sensors were first calibrated against lake bed sediment in lab conditions then jointly

used to estimate suspended sediment mass fluxes. Samples were analyzed to estimate the grain size distribution in different parts of the lake bottom and the water body. A number of sediment collecting tubes, used also earlier, facilitated to determine vertical sediment fluxes in prevailing wind conditions. The analyses confirmed that the bottom sediment often presents the character of cohesive mud due to the large amount of fines, mainly clay. Cohesive sediments, especially when being subject to alternating consolidation and fluidization, need special care both in analysis and modeling. Based on the data analysis, a multi-fraction-suspended sediment transport model was developed to handle different grain size ranges separately rather than looking for one single diameter to represent the whole spectrum. To identify zones with various sediment dynamic parameters, a detailed penetrometer surveying of the study was also carried out. By means of all this, it became possible to reproduce the selective bottom erosion and deposition processes resulting in large bay- and lake-wide irregularities in the bottom sediment distribution. Such modeling tools have been utilized to support a number of projects to perform dredging and improve water quality since then.

Conclusion

Based on the pioneering measurements and observations of the 1960s and 1970s and to the rapid development of instrumentation and informatics starting in the 1980s, in 1990s significant progress was achieved in understanding and simulating the decisive parameters of the most important hydro- and sediment dynamic processes of Lake Balaton. The maintenance of the hydrological, chemical, and biological balance of the lake and the design of yacht marinas have mostly profited from the research results.

BALTIC SEA BASIN, SINCE THE LATEST DEGLACIATION

Thomas Andrén
School of Life Sciences, Södertörn University,
Huddinge, Sweden

Introduction

The Baltic Sea basin is one of the world's largest intra-continental basins, occupying 373,000 km² with a drainage area four times its size. Its mean depth is c. 54 m, although a few relatively deep basins exist, e.g., the Eastern Gotland basin (248 m) and the Landsort Deep (459 m) (Figure 1). The Baltic Sea basin has served as a depositional sink throughout at least the last several hundred thousand years, and its sediments comprise a unique high-resolution archive of the paleoenvironmental history of the huge drainage area, the basin itself, and neighboring sea areas. These sediments also constitute the base for the reconstruction of the Baltic Sea basin since the Last Glacial Maximum about 20,000 years ago, and the development of the Baltic Sea basin since then has been controlled by land uplift, the result of the down pressing of the crust from the Scandinavian ice sheet, and the fluctuations in the global sea level. This has resulted in what we can distinguish as several developmental stages of the Baltic Sea basin, both freshwater and brackish water stages, alternatingly, namely the Baltic Ice Lake stage, the Yoldia Sea stage, the Ancylus Lake stage, and the Littorina Sea stage. Despite the fact that the Baltic Sea basin has a fairly long history, the present Baltic Sea is a stage in the development since the Last Glacial Maximum, which is a relatively short time from a geological perspective.

The Baltic Ice Lake stage

The oldest stage in the history of the Baltic Sea began when the Scandinavian ice sheet started to melt and the ice margin retreated northwards. As the ice sheet retreated from the southern Baltic Sea basin, it left an environment probably comprising several small melt water lakes dammed between huge areas with grounded icebergs and blocks of dead ice that had broken off from the retreating ice margin. This is how we believe the

environment was in the southern Baltic Sea basin some 15,000–16,000 years ago (Houmark-Nielsen and Kjær, 2003).

In front of the retreating ice margin c. 14,500 years ago, a large, continuous melt water lake formed, the Baltic Ice Lake, which had an outlet through the Öresund strait. After about 500 years the erosion of Öresund strait reached down to the bedrock threshold, located at 7 m depth, which stopped further erosion. Land uplift of the ice-free southern Sweden raised the threshold over the ocean level and the outlet could be described as a giant waterfall. Differences in the land uplift south and north of the sill area resulted in a rise of the Baltic Ice Lake water level in areas south of the outlet, in southern Denmark, Germany, and Poland. In the newly ice-free areas north of the Öresund strait, land uplift was so strong that no rise of the shoreline has been registered.

About 14,000 years ago the ice margin ran from south central Sweden relatively straight east over the Baltic Sea basin and to central Estonia.

The ongoing melting led to more water being added to the Baltic Ice Lake, but its surface was relatively stable since the threshold at Öresund acted as an overflow. Then, about 12,800 years ago, the shorelines suddenly fell in eastern Småland by about 5 m and by as much as 10 m in Blekinge (Björck, 2008). This means that the Baltic Ice Lake sought a new outlet for a relatively short period.

The location of this outlet has been the subject of much debate among Nordic geologists, and connections between the Öresund strait and the Baltic Sea basin or the White Sea have been proposed but found unlikely. The most likely scenario seems to have been an outlet through southern central Sweden. A model has been developed where the ice edge retreats a short distance north from Mount Billingen's northern tip and thus opens a connection between the Baltic Ice Lake and the North Sea (Björck and Digerfeldt, 1984).

In the sediments from this time there are no signs that salt water entered the Baltic Sea basin, which indicates that this connection only existed for a short period and served only as an outlet for the Baltic Ice Lake. As result of this lowering of Baltic Ice Lake surface, for the first time since the ice sheet began to melt a land bridge formed between southern Sweden and the continent, which must have facilitated the migration of plants, animals, and humans.

The climate warming that had been ongoing since the ice sheet began to melt was interrupted by an approximately 1,300-year long cold period (Younger Dryas) that began about 12,900 years ago. It is possible that the drainage of Baltic Ice Lake together with the drainage of the giant Lake Agassiz in North America contributed to this cold period. The large amounts of freshwater from these two ice lakes might have disturbed the North Atlantic deep water circulation significantly, thus resulting in a cooler climate. The ice sheet began advancing southwards and the outlet at Billingen was closed by the advancing ice.

Baltic Sea Basin, Since the Latest Deglaciation, Figure 1 Map of the Baltic Sea and its surroundings. The numbers refer to sites mentioned in the text. 1 = Landsort Deep; 2 = Eastern Gotland Basin; 3 = Öresund strait; 4 = Småland; 5 = Blekinge; 6 = Mount Billingen; 7 = Bornholm; 8 = Arkona Basin; 9 = Bornholm Basin; 10 = Hanö Bay; 11 = Stockholm; 12 = Gotland; 13 = Lake Mälaren; 14 = Svea River/Svea Falls; 15 = Lake Vänern; 16 = Göta River; 17 = Steinelve/Otteid strait; 18 = Darss Sill; 19 = Dana River; 20 = Great Belt; 21 = Öland; 22 = Södertörn.

As a result, the Baltic Ice Lake water level started to rise up to the level of the Öresund strait threshold and southern Sweden experienced rising shorelines. The ice-free areas north of the Öresund area had a stable or slightly falling water level. These differences are due to land uplift occurring at different rates. In the south, the uplift was slower than the Öresund strait threshold, whereas in the north it was faster.

The elevation of the shoreline in the south began about 12,500 years ago and resulted in the water level of Baltic Ice Lake coming to be level with or slightly above the

threshold in the Öresund strait, a condition that seems to have prevailed over the rest of the Baltic Ice Lake's existence (Figure 2).

At the end of the cold Younger Dryas event the ice sheet once again began to melt more than it grew and the front retreated northward. This meant that the Baltic Ice Lake came to an abrupt end when the ice front for a second time left the northern tip of Mount Billingen and the connection between the Baltic Sea basin and the North Sea re-opened. The level of the Baltic Ice Lake dropped very quickly, perhaps only over a year or two, almost 8,000 km³ of fresh

Baltic Sea Basin, Since the Latest Deglaciation,
Figure 2 Palaeogeographic map showing the Baltic Ice Lake immediately prior to its maximum extension and final drainage about 11,700 years ago.

water was released and the water level dropped by 25 m (Strömberg, 1992; Jakobsson et al., 2007). To get an idea of how much freshwater entered the North Atlantic it can be compared to today's Baltic Sea, which holds approximately 21,000 km³ of water. This happened about 11,650 years ago (Andrén et al., 1999, 2002). The short pulse of freshwater can be detected in sediment cores on the Swedish west coast and further out in the Skagerrak (e.g., Miller, 1982; Erlenkeuser, 1985; Bodén et al., 1997). However, it seems as if it had only a small effect on the circulation in the North Atlantic.

This drainage marks the end of the Baltic Ice Lake and the start of the next stage, the Yoldia Sea stage.

The Yoldia Sea

The final drainage of the Baltic Ice Lake at Mount Billingen occurred just before a very exciting time in climate trends since the last glaciation. It was the transition from the cold Younger Dryas to the warm Preboreal about 11,700 years ago. The temperature rise may have been as high as 12° in just 50 years, and this obviously had consequences for the Scandinavian ice sheet covering parts the Baltic Sea basin in several ways. Much more melt water was produced than in the past, and this resulted in an increasing volume of water flowing out of the basin; therefore, no salt water inflows occurred during the first 250 years after the opening of the passage westwards.

Furthermore, as consequence of the increased melting of the ice sheet, its front retreated northwards much faster than before. In connection with this great drainage and the lowering of the Baltic Ice Lake surface by 25 m, as much as 70,000 km² of new land was created. These earlier lake beds consisted of very unstable sediments. Reworked by waves and bottom currents these sediments were redeposited on the Yoldia Sea bottoms and mixed with the sediments that were transported by the melt water from the retreating ice sheet. This resulted in thicker glacial varves being deposited during the early Preboreal time than during the Younger Dryas.

The new low level of the Yoldia Sea immediately after drainage meant great change for the southern Baltic Sea basin. Among other things, the former outlet through Öresund strait closed and a wide land bridge formed between Sweden and Denmark. The major Danish islands came to form a contiguous landmass directly connected with Germany. The island Bornholm was associated with the German mainland via a land bridge, and the German and Polish coastlines were located much further north than today. In Arkona Basin, Bornholm Basin, and in Hanö Bay the shoreline at this time was located at a level 35–50 m lower than today. In Hanö Bay we still can find today stumps on the sea bottom as a reminder of the pine trees that once grew on these low levels.

About 11,300 years ago salt water from the North Sea flowed into the Baltic Sea basin during a period of no more than a maximum of 300 years (Andrén et al., 2007). There are at least two explanations for why it happened at just this time. First, the continued retreat of the ice sheet led to a much wider passage through straits in south-central Sweden, which of course facilitated the inflow of salt water. Second, this period coincided with a small decline in the climate, which had become much warmer after the drainage of the Baltic Ice Lake. This drop in temperature, referred to as the Preboreal Oscillation, may in turn have resulted in the amount of melt water produced by the ice sheet decreasing. This allowed the salt water from the North Sea to penetrate into the Baltic Sea basin. The salinity of the Baltic Sea during this phase of the Yoldia Sea caused the glacial clays deposited during this time to be only weakly varved clay as a result of the flocculation of clay particles in the salt water environment (Andrén et al., 2002).

The nutrients the inflowing saltine water brought into the basin resulted in the production of both zoo- and phytoplankton for the first time after the deglaciation. This is visible as a small increase in the amount of organic carbon in sediments. Fossil shells of mollusks, ostracods and microscopic plant plankton (diatoms) are found in the clays from this stage (Andrén and Sohlenius, 1995; Wastegård et al., 1995; Andrén et al., 2000a). This stage in the development of the Baltic Sea is named after fossil findings of the arctic mollusk *Yoldia arctica* (nowadays renamed *Portlandia arctica*). Black bands of monosulfides in the sediment deposited at the sea bottoms of the Yoldia Sea indicate that a salinity

Baltic Sea Basin, Since the Latest Deglaciation,
Figure 3 Palaeogeographic map showing the Yoldia Sea at the end of the brackish phase about 11,100 years ago.

stratification was developed, preventing the water masses that mix vertically, which leads to oxygen deficiency on the bottoms. Other examples of fossils in the clays deposited in the Yoldia Sea are almost complete skeletons of both harp seal and ringed seal in central Sweden. There are also reports on the findings of a cod fish, probably whiting, in a clay pit in the Stockholm area (De Geer, 1913). After studies of the fossil diatom flora we know that this brackish phase of the Yoldia Sea ended about 11,000 years ago and that at this time the surface water throughout the basin was slightly brackish, much like in today's Gulf of Bothnia (Andrén et al., 2000a, 2002) (Figure 3).

In sediments that are 100 years younger, we find no trace of a brackish environment (Andrén et al., 2000a). The ongoing uplift of the straits in south central Sweden led to the passage becoming narrower and, as a result, salt water inflows decreased, which led to a freshening of the Yoldia Sea. In the Lake Vänern basin, which was part of the Baltic Sea basin, however, we can see traces of marine influence for the remainder of the Yoldia Sea stage. With time, however, the straits in south central Sweden became so narrow and shallow that the Yoldia Sea water level began to rise in pace with the uplift of the straits. The first signs of a rising shoreline in the southern Baltic Sea basin and the next stage of the Baltic Sea development began 10,700 years ago. To summarize the Yoldia Sea stage, it

started out as a melt water lake during the first 350 years of existence, followed by a short phase of brackish water conditions and after 300 years it turned back to freshwater conditions. Although this 1,000-year stage of Baltic Sea development was, for the most part, characterized by freshwater, a somewhat illogical historical division of the Baltic Sea stages, with the lake and sea stages, has been retained. The short time that seawater flowed into the Yoldia Sea has apparently been important for the development of biological life in Baltic Sea basin.

The Ancylus Lake stage

During investigations on the island of Gotland at the end of 1800s, Swedish geologist Henrik Munthe found fossils of the freshwater snail *Ancylus fluviatilis* in sediment layers located between the layers from the weakly brackish Yoldia Sea and the brackish Littorina Sea. This gave him evidence of a new freshwater stage of Baltic Sea development. However, it was Gerard De Geer who later gave this Ancylus Lake stage its name. More recently, in further analysis done on the sediment layers containing *Ancylus fluviatilis* the proposed freshwater environment has been confirmed by findings such as a fossil freshwater diatom flora. Both *Ancylus fluviatilis* and the recorded siliceous microfossils exists today, the snail in rivers and the diatoms in lakes such as Lake Mälaren.

The Ancylus Lake stage remains the least known of the Baltic Sea stages and most difficult to understand the evolution of.

In the early 1900s it was discovered what was assumed to be Ancylus Lake outlet westwards, and it was named the Svea River. By studying the older shorelines, raised by the uplift, it was assumed that the Ancylus Lake water level was between 15 and 30 m higher than that of Lake Vänern in west. It was then concluded that the outlets of the river were a series of powerful waterfalls, the Svea Falls, in the northeastern part of the Lake Vänern basin. More modern research has found clays of Yoldia Sea age in the supposed discharge area and consequently no erosion has occurred during Ancylus Lake time. It can thus be concluded that the water depth in this area must have been significant at this time and that Lake Vänern was part of Ancylus Lake and became isolated from the North Sea at about the time the Ancylus Lake water level began to rise. The Ancylus Lake was then dammed with a water level above the North Sea area, but its outlet must be found west of Lake Vänern. Today we believe that the outlets were located in the Göta River and Steinälva/Otteidstrait, and that the Ancylus Lake water level began to rise when the uplift of these outlet areas made both of them narrower and shallower.

As a result of the fact that the land uplift was greater in the areas in north where the ice sheet just recently melted, the Ancylus Lake level came to rise rapidly in the southern part of the Baltic Sea basin where the uplift was slowing down. In the very southern Baltic, submerged pine trees and peat deposits dated to between 11,000 and 10,500 years ago are evidence of a transgression

Baltic Sea Basin, Since the Latest Deglaciation,
Figure 4 Palaeogeographic map showing the Ancyclus Lake during the maximum transgression about 10,500 years ago.

(Andrén et al., 2007) (Figure 4). The rise of the water level in this area may have been as fast as 5–10 cm a year. The total increase of the water level in this area was as much as 25 m and the rise continued until about 10,300 years ago, when its highest level was reached. One result of this rapid increase of the water level was that the pine trees that grew in Hanö Bay came to be drowned in just few 100 years.

North of a line running from the southern Lake Vänern through south central Sweden and further eastwards across the Baltic Sea towards the Finnish south coast, no records of a rising Ancyclus Lake water level are to be found, as land uplift is the dominant process in these areas.

The Ancyclus Lake water level in the southern Baltic Sea basin came to be at least 10 m above the North Sea's present sea level, but in less than 200 years its level was lowered to sea level at the time (Björck et al., 2008). How did this happen?

The traditional view has been that a southern threshold in the Darss Sill area in the southern Baltic Sea basin was flooded and began to erode. The Ancyclus Lake could then drain into the Kattegat through the Great Belt and its surface was lowered to the level of the North Sea. This drainage system has been called the Dana River (von Post, 1929). The reason for a drainage system like this is the difference in the uplift of the Öresund strait, which has served as outlet before, and the Darss Sill area shifted

the lowest point southwards to northern Germany. It has further been thought that when the outlet in the south started the initial outlets through central Sweden were still active, but they should have closed relatively quickly when the lowering of the lake level was so quick. The shallower these initial outlets become, the more water must be drained via the Dana River. There are also deposits on the seabed of the Great Belt, which indicates both high material transport and high current speeds (Novak and Björck, 1998). A great Dana River, as outlined above, has been proven unlikely as the threshold on the sea bottom in the Darss Sill area is too shallow (e.g., Bennike et al., 1998; Jensen et al., 1999; Lemke et al., 1999; Lemke et al., 2001). Today, it is believed that the southern outlet of the Ancyclus Lake was characterized by a variable fluvial environment, creating fluvial, levee, and lacustrine deposits, i.e., more of a calm water environment than a river-type water flow (Björck et al., 2008).

As a consequence of the new outlet in the south, the Danish so-called mainland time was over and the initial spillway through central Sweden became dry and, for the first time since the ice sheet melted, there was a land bridge between the southern and northern Sweden created.

Although today we are not entirely clear on where the Ancyclus outlet was located and configured, we know that its surface was level with North Sea about 10,000 years ago, and that the outlet must have existed somewhere in the south. The rising sea level at this time resulted in weak, short, and sporadic pulses of inflowing marine water, starting some 9,800 years ago and passing through the same pathway. This can be seen in the composition of the fossil diatom flora in sediments from both Bornholm Basin and along the Blekinge Coast (Andrén et al., 2000b; Berglund et al., 2005). The same inflows were also recorded in sediments from eastern Gotland Deep, but much weaker than in the Bornholm Basin (Andrén et al., 2000a). This suggests that influx emanated in the southernmost part of the Baltic basin. In the southern Baltic, these inflows mark the beginning of the next stage in the development of the Baltic Sea, but for the central and northern Baltic Sea, it took another 1,000 years before the salt water inflows became so strong and long-lasting that these areas were affected.

The Littorina Sea stage

When the climate became warmer and the last glacial period ended, the Earth's ice sheets began to melt. The melt water was added to the oceans and the global sea level began to rise, at times by as much as 2 cm/year. About 10,000 years ago, a connection between the Baltic Sea and the oceans was established and marine water started to flow into the Baltic Sea. These inflows occurred through the passages that are still active today for water exchange with the North Sea, i.e., in the beginning Great Belt and later also the Öresund Strait. This is the beginning of a 2,000-year-long period of relatively low and fluctuating salinity in the southern Baltic

Sea (Andrén et al., 2000b); a transitional period in Baltic Sea development is sometimes referred to as the Mastogloia Sea.

When the contact between the Baltic Sea and the oceans was established, the water level around the Baltic Sea rose due to the local land uplift and the rising sea level. In the southern part of the Baltic Sea basin this meant a rising sea level – a so-called transgression – which led to even more abundant inflow of salt water. About 8,000 years ago the water depth at Öresund was similar to today, and in the southern Baltic Sea the salinity was approximately the same as today. After another 500 years, brackish water conditions also prevailed in the central Baltic Sea. Sediments from the German coast deposited during this time contain fossil shells of the marine snail *Littorina littorea*. This snail has also given its name to this stage of the Baltic development, Littorina Sea.

The continued rise in global sea level meant that the depth of water in the Öresund and Great Belt became greater than today, and in the Baltic Sea the first so-called Littorina transgression was started. It culminated 6,500 years ago when the Littorina Sea level was about 5 m above today's sea level in southernmost Sweden (Figure 5) (Berglund et al., 2005; Yu et al., 2007).

A fluctuating sea level is something that seems to have characterized the southern Baltic Sea during Littorina Sea stage. Today the best way to study these sea level changes

is along the southern Baltic Sea coasts, where land uplift during the Littorina Sea period was small and the dominating component in shoreline changes was change in sea level. There are up to six different transgressions recorded in sediments of the Littorina Sea stage age (Berglund et al., 2005). Even on the islands of Öland and Gotland, along the coast of Småland (Svensson, 1991), at Södertörn (Risberg, 1991), and in the south of Finland the Littorina Sea transgression are documented. Along the coasts of the Bothnian Sea and the Gulf of Bothnia there is no transgression registered, since the land uplift in this area throughout Littorina Sea stage was greater than the sea level rise.

As the marine- and nutrient-rich water started to flow into the Baltic Sea basin, algae and phytoplankton began to thrive. Large amounts of organic material from dead organisms were deposited on the sea bottom where the oxygen was consumed during decomposition. Approximately 7,500 years ago, laminated sediments were deposited over large bottom areas in the central Baltic Sea, which means that the bottoms had completely oxygen-free conditions and no burrowing organisms could live there (Sohlenius and Westman, 1998; Andrén et al., 2000a; Sohlenius et al., 2001; Zillén et al., 2008). So-called “dead bottoms” were created. This also suggests that the vertical water mixing was missing, indicating the presence of salinity stratified water masses, a halocline was established. Conditions like this are very similar to today's Baltic Sea bottom conditions. An additional 1,000 years later these conditions also prevailed in the Bothnian Sea and Bothnian Bay.

We also know from studies of these laminated sediments that blue-green algal (cyanobacteria) blooms were common in the early Littorina Sea stage (Bianchi et al., 2000; Borgendahl and Westman, 2007). They might even have been stronger than today's much-discussed blooms. This can be determined from the sediment's preserved pigment residues from cyanobacterial algae. Such fossil pigment residues have been found in sediments from both the southern and central Baltic Sea. Sediments from the Bothnian Sea and Bothnian Bay have not yet been investigated, but blooms may have been occurring there also during this time. Conditions during the early Littorina Sea times, with high temperature, relative calm, low salinity (blue-green algae require a salinity of no more than 11.5%), and small competition with other algal groups (such as diatoms, which are found very sparingly in the sediments deposited during this time), apparently favored these blooms.

From the fossil diatom flora we know that the salinity of the Baltic Sea about 6,000 years ago was higher than today (Andrén et al., 2000a, b). This may have been an effect of a larger inflow of marine water through the straits in the south, probably a greater evaporation due to a higher insulation during summer and lower inflow of freshwater by the rivers. We currently do not know exactly how much higher salinity the Littorina Sea had. Results from studies of oxygen isotopes in fossil shells from the Gulf of

Baltic Sea Basin, Since the Latest Deglaciation,
Figure 5 Palaeogeographic map showing the Littorina Sea during the most saline phase at about 6,500 years ago.

Finland, however, indicate about 4% higher salinity than today (Donner et al., 1999).

The time when the salinity of the Baltic Sea was highest coincides with the warmest time since the last Ice Age, the so-called postglacial climate optimum. At that time trees such as oak, linden, and elm, which required a warm climate, grew in southern parts of northern Sweden. Since this time, the salinity of the Baltic Sea decreased to present-day levels, and it is said that the actual Littorina Sea stage ended 3,000 years ago. The climate also became colder, except during the Medieval Warm Period. This was a warm period that occurred 900–1300 AD, and it is known that the Scandinavian Vikings settled in Greenland and that grapes species grew in England that today grow in northern France. For the Baltic Sea it meant that, once again, times of high production of algae and phytoplankton. Once these fell to the sea bottom, the oxygen was consumed, anoxic bottom conditions prevailed, and the areas displaying laminated sediments increased (Andrén et al., 2000a; Leipe et al., 2008). It also appears that intense blue-green algae were common during this time. This warm period was followed by a colder one, the so-called Little Ice Age. This cold phase also resulted in warm-demanding diatoms species disappearing from the Baltic Sea flora, and they have not reappeared since (Andrén et al., 2000a, b).

The present Baltic Sea

The latest 1,000 years of Baltic Sea development, with a salinity similar to today's, has sometimes been called *Mya* Sea, after the North American sand clam *Mya arenaria*. They may, in their larval stage, have been transported in ballast water of merchant ships into the Baltic Sea. It was previously believed that the species came over from North America when the Atlantic races started in the 1500s. Danish colleagues have shown using radiocarbon dating of the earliest *Mya* shells that they are of Viking age (Petersen et al., 1992). Further evidence that the Vikings were in North America long before Columbus!

Ever since humans began to use the land around the Baltic Sea they have interfered with the natural environmental evolution. One old example of this is the occurrence of specific lead isotopes emanating from human lead use and atmospherically transported and subsequently deposited in the Baltic Sea sediments. This dates back to as early as when the major use of lead shifted from the Iberian peninsula to Germany, the French alps, and the British Isles in the first to third centuries AD (Bindler et al., 2009).

Even though it cannot be expected that the Baltic Sea a 100 years from now will look the same as the present Baltic Sea as a result of ongoing natural phenomena, it must be stressed that the present pressure put on its ecosystem by humans is much larger than the natural processes involved.

BASIN-SCALE INTERNAL WAVES

Damien Bouffard, Leon Boegman

Department of Civil Engineering, Queen's University,
Kingston, ON, Canada

Definition

Basin-scale periodic waves propagating on a thermocline or other subsurface density interface.

Introduction

The complex hydrodynamic processes in lakes mainly result from a competition between surface heat flux and wind stress. While the former sets up stabilizing density stratification during summer and winter (beneath ice cover), the action of the latter, on the stratification, leads to internal waves of various temporal and spatial scales that drive irreversible turbulent mixing. Roughly 20% of the wind energy entering the lake is transferred to large-scale wave motions, called basin-scale internal waves (hereafter BSIW) – the remainder being dissipated in the surface layer. These waves temporarily store the wind energy until it is dissipated, mainly by friction along the lake bed. They play a crucial role in the transport of mass and momentum in the lake, driving horizontal dispersion and vertical mixing with great implications for biogeochemical processes and contaminant transport. This article quantitatively describes BSIW dynamics, with particular illustrations from Lake Simcoe (Canada), and provides a framework for the reader to recognize and analyze BSIWs in observational data.

BSIW are characterized by the basin shape, the stratification (See [Stratification in Lakes](#)), and the influence of the Earth's rotation. Typical periods of BSIW range from days to hours ([Figure 1b](#)) and are long compared to periods of surface seiches, which have periods of minutes to hours, and wind waves, with periods of seconds.

Generation of basin scale internal waves

To describe the generation of these waves, we start with a simple rectangular lake of length, L , width, B , and depth, H , with a sharp thin thermocline separating a homogenous warm epilimnion of thickness h_1 and density ρ_1 and from a homogeneous cold hypolimnion of thickness h_2 and density ρ_2 ([Figures 1a](#) and [2a](#)). A steady wind applied to the lake surface ([Figure 2a](#)) causes an upwelling (setup) of the free surface and a downwelling of the thermocline at the downwind shore. If the wind forcing lasts for more than a quarter of the fundamental mode-one BSIW period (defined below), the thermocline tilt will span the entire basin with a maximum amplitude $\eta_o = \frac{Lu_*^2}{g'h_1}$, where $g' = g(\rho_2 - \rho_1)/\rho_2$ is the reduced gravity as a result of the density difference across the thermocline. The wind stress on the surface is captured by the shear velocity $u_* = \sqrt{\rho_a/\rho_1 C_D W_{10}^2}$, where the wind, W_{10} , is

Basin-Scale Internal Waves, Figure 1 (a) Typical summer temperature profile in Lake Simcoe. The solid line represents a profile where the two layers assumption is valid. The dashed line profile allows more than vertical mode-one with a continuous stratification. (b) Power spectra of thermocline displacement from a temperature chain mooring located in Lake Simcoe, showing basin-scale internal waves with periods of $T = 95$ h and $T = 14$ h. These periods vary during the season with the change in stratification. (D. Bouffard and L. Boegman, unpublished). Raw temperature data provided by D Evans.

measured 10 m above the lake surface, and $\rho_a = 1.2 \text{ kg m}^{-3}$ is the air density and $C_D \sim 10^{-3}$ is a drag coefficient (Figures 1 and 2).

The gravitational force acting on the tilted interfacial free surface and thermocline generates both surface (barotropic) and internal (baroclinic) pressure gradients, which balance the applied wind force. When the wind stops, the gravitational force is unbalanced and the interfaces relax, generating freely propagating basin-scale internal and surface waves, from both upwind and downwind ends of the lake. The upwind and downwind components combine to form basin-scale standing waves on both interfaces, referred to as surface and internal seiches (See *Internal Seiches*).

A single wind burst or aperiodic wind events lead to free modes with natural periods that depend on the basin shape, the stratification, and the Earth's rotation. Conversely, periodic wind forcing (e.g., sea breeze) systematically resets the phase of the wave, leading to forced BSIWs with periods that match those of the wind forcing (e.g., Lake Kinneret, Gomez-Giraldo et al., 2006).

Horizontal pattern of BSIW

A two-layer system is a good approximation for most lakes at mid-latitude during the late summer (Figure 1a), and we treat the horizontal distribution of BSIW in this case. When the wind relaxes, the oscillation takes the form of a sinusoidal standing wave with antinodes at either end of the basin. The motion is described by the linear shallow water equation, the wave speed $C = \sqrt{g'H_e}$, where

$H_e = h_1 h_2 / (h_1 + h_2)$, the equivalent depth. C depends on the stratification and will change during the season as the thermocline deepens. Different horizontal wave modes can be excited, in the lake, as long as they match the antinodal boundary condition (Figure 2b), and the different periods associated with the horizontal modes are $T_n = 2L/nC$, where n is the number of nodes in the horizontal (i.e., the horizontal mode). The periods of the waves are thus dependant on the stratification (through C) and the basin size, potentially tuning the BSIW into and out of resonance with periodic wind forcing (Antenucci and Imberger, 2003). The first horizontal mode can contain up to 98% of the energy embodied in the initial wind-induced thermocline tilt, but basin shape and/or wind forcing can enhance the importance of secondary modes in some cases (Münnich et al., 1992; Boegman et al., 2005).

Vertical pattern of BSIW

A diffuse seasonal thermocline (metalimnion) with a continuous stratification (Figure 1a dashed line), or the presence of both seasonal and diurnal thermoclines, allows vertical basin-scale modes to be generated in addition to the horizontal modes. The wave motions are described by the Storm-Liouville eigenvalue equation (Gill, 1982; Mortimer, 1974), which is typically solved numerically to obtain a set of phase speeds corresponding isotherm displacements (wave functions) for possible vertical modes. The most energetic mode is generally the vertical mode-one, where currents oscillate in the opposite directions in the epilimnion and the hypolimnion inducing a significant shear through the thermocline (Figure 2a). Higher vertical modes are usually due to an upwind-downwind asymmetry in the tilting and are found to become dominant when their period is resonant with the wind period, $T_{n,m} = 2\pi(1 + (mL/nH)^2)/N$, where m is the vertical mode, $N^2 = -(\frac{g}{\rho})(\frac{d\rho}{dz})$ is the Brunt-Väisälä frequency, and z is the vertical coordinate direction. The vertical mode-two wave is characterized by an expansion and subsequent compression of the metalimnion generating a thermocline jet in the opposite direction as the current in the epilimnion and the hypolimnion (Figure 2c). The vertical mode-one seiche will have a strong impact on the bottom boundary biogeochemical dynamics (e.g., sediment resuspension) as it flows along the lake bed, while the vertical mode-two seiche will affect mixing and biogeochemistry through the thermocline (e.g., phytoplankton maximum, oxygen flux).

Effects of the earth's rotation

In large lakes, the Coriolis force, resulting from the Earth's rotation, becomes significant and can modify the wave pattern. The relative importance of the Coriolis force is quantified with the Rossby radius, $Ro = C/f$, and the Burger number, $S = \frac{Ro}{R}$, where $f = 4\pi/T \sin \theta$ is the Coriolis parameter, $T = 1$ day is the period of rotation of

Basin-Scale Internal Waves, Figure 2 Sketches of (a) horizontal mode-one vertical mode-one, V1H1 internal seiche, (b) horizontal mode-two vertical mode-one, V1H2, and (c) horizontal mode-one vertical mode-two, V2H1. Dashed lines represent thermocline at rest. Dark gray color represents the thermocline separating the warm epilimnion (1) and the cold hypolimnion (2). Thin arrows show the direct response of the lake to wind stress. Thick arrows show the wave-induced currents after the wind. (d) Kelvin wave traveling in the x direction with the shore located to the right. The amplitude of the Kelvin wave decreases exponentially offshore as $\eta = \eta_0 e^{-y/R_0} \cos(kx - \omega t)$. (e) Poincaré wave in an infinite basin. Inertial circles are shown beneath the wave. Panels (d) and (e) are reprinted from Mortimer (1974).

the Earth, θ is the latitude, and R is a typical lengthscale characterizing the basin length or width (usually $L/2$). For lakes with $R > R_0$, $S < 1$ and rotational effects are expected. Conversely, in the case $S > 1$, rotational effects can be neglected.

We illustrate the effects of rotation on BSIWs by considering its influence on a longitudinal internal seiche in a large northern hemisphere lake. As the wind-displaced thermocline relaxes, and the seiche begins to propagate across the basin, the Coriolis force pushes the wave toward the right, where it is bounded by the shoreline, causing it to propagate cyclonically (counterclockwise in the northern hemisphere) along the shore with the wave amplitude decaying exponentially in the offshore direction (Figure 2d). This wave is called a Kelvin wave, and its

period must be greater than the local inertial period, $T_i = 2\pi/f$. The phase velocity and corresponding wave period, T_l , remain the same, for the Kelvin wave, as in the non-rotational case. At a distance of $2R_0$ offshore, the wave is only 10% of its maximum amplitude, so in very large lakes, such as the Laurentian Great Lakes, where $R \gg R_0$, the Kelvin wave is a nearshore phenomenon that takes the form of a coastal jet. In smaller lakes, where $R \sim R_0$, the Kelvin wave signature can be found throughout the basin (e.g., Lake Simcoe).

We now consider the effect of rotation on the transverse basin-scale internal seiche. Because $L > B$, contrary to the longitudinal seiche, the transverse seiche is not constrained by the boundaries at the longitudinal ends of the lake. When deflected to the right, by the Coriolis

force, the seiche is, therefore, modified into a progressive anticyclonic (clockwise in the northern hemisphere) waveform. Fluid particles displaced by the wave follow anticyclonic circular or elliptical trajectories (Figure 2e), known as inertial circles, with radius $r_i \sim u/f$, where u is the wave-induced current speed. These transverse waves are called inertia-gravity waves or Poincaré waves, and the dispersion relation for a rectangular basin, in terms of the wave period, is given by: $1/T_{PW}^2 = 1/T_i^2 + (1 + r^2)/T_1^2$, where $r = B/L$ is the basin aspect ratio at the thermocline depth (Mortimer, 2004). The dual character of this wave can be seen in the dispersion relation, where the first term on the right-hand side describes the inertial behavior of the inertial circles, and the second term has gravitational wave behavior with rectilinear motion. This explains the elliptical pattern of the Poincaré wave with the eccentricity depending on the relative intensity of these two terms. The dispersion relation (above) shows that the Poincaré wave period is typically close but always lower than the inertial period, the shift being a function of the basin shape (through r) and the stratification (through T_1) and can therefore be expressed as a function of S (Antenucci and Imberger, 2001) with the same trend of T_{PW} approaching T_i (inertial wave behavior) as S decreases (i.e., large lake).

In large lakes, the coastally trapped Kelvin wave has the strongest wave currents near and running parallel to the boundary (Figure 2c), where the thermocline intersects the lake shore. Here, the Poincaré wave signal is weak

because the no-flux boundary condition causes the inertial circles flatten, becoming shore parallel. Poincaré waves, and the associated currents are, therefore, predominantly found within the basin interior and are best identified in the field by computing rotary spectra of the current and looking for a peak $< T_i$ in the clockwise spectra only.

BSIW damping processes

BSIW energy is ultimately damped by dissipation (friction) and the work required by diapycnal mixing (See *Mixing in Lakes*). The processes responsible for dissipation and mixing can be linked to external driving factors, such as wind, stratification, and basin shape, which energize the waves, using the dimensionless Wedderburn number, W .

The magnitude of the wind-induced thermocline setup can be quantified according to $W = \frac{h_1}{\eta_0}$, which is the ratio of the restoring baroclinic pressure force (i.e., gravitational force acting on the tilted thermocline) to the applied wind force. The Wedderburn number is commonly expressed in inverse form $W^{-1} = \frac{\eta_0}{h_1}$ so as to capture the increased tilt of the thermocline with increasing wind stress.

In the case of linear BSIWs, $W^{-1} < \sim 0.3$ (Figure 3), 90% of the wave energy is dissipated by friction as the seiche-induced currents oscillate along the bottom boundary (Imberger, 1998; Wüest et al., 2000) (Figure 2). These currents generate a turbulent bottom boundary layer and shear instabilities (e.g., Kelvin-Helmholtz billows)

Basin-Scale Internal Waves, Figure 3 Damping regimes as a function of W^{-1} and the ratio h_1/H . (Reprinted from Horn et al., 2001.).

Basin-Scale Internal Waves, Figure 4 Evolution of the 15°C isotherm, representing the thermocline displacement in Lake Simcoe from a three-dimensional hydrodynamic simulation (ELCOM). (a) Data have been band pass filtered around the 95-h Kelvin wave period. Each image is offset by a quarter of Kelvin wave period (~ 24 h) and shows the counterclockwise evolution of the wave. (b) Data have been band pass filtered around the 14-h Poincaré wave period. Each image is offset by a quarter of Poincaré wave period (~ 3.5 h) and shows the clockwise evolution of the wave. The *black dot* in each panel highlights the rotation of the wave crest, and the *black circle* represents the time evolution (D. Bouffard, and L. Boegman, unpublished).

form where the thermocline oscillates in a swash zone along the lake bed. During summer, the boundary layer is the primary source of turbulent mixing in hypolimnion and across the thermocline, thus strongly influencing biogeochemistry (Wüest et al., 2000). For $\sim 0.3 < W^{-1} < \sim 1.0$ (Figure 3), the BSIWs begin to lose energy to smaller-scale nonlinear internal waves, e.g., solitary waves (Boegman et al., 2005), which propagate with little energy loss until they shoal and break on sloping topography at the depth of the thermocline, leading to localized dissipation, mixing, and sediment resuspension. Under conditions of strong force and weak stratification, $W^{-1} > \sim 1.0$, BSIWs will degenerate through the formation of internal hydraulic jumps (MacIntyre et al., 2009) and/or shear instability in metalimnion of the basin interior where the Richardson number, $Ri = N^2 / (du/dz)^2 < 1/4$. The instabilities generate mixing in the thermocline region, locally entraining fluid from the epilimnion and hypolimnion causing the remaining 10% of BSIW energy dissipation. Detailed quantifications of the energy flux paths in lakes can be found in (Imberger, 1998; Wüest et al., 2000; Boegman et al., 2005).

Case study: Lake Simcoe

To illustrate the practical use of these equations, we apply them to Lake Simcoe (Canada). During summer, the lake is characterized by $h_1 = 13$ m, $h_2 = 15$ m, $T_1 = 16$ C, and $T_2 = 8$ C (Figure 1). Due to the presence of the long narrow and deep Kempenfelt Bay in the western part of the lake (Figure 4), there are two characteristic lengthscales. The longitudinal scale, which includes the bay $L = 40$ km, while the main basin is $L = 20$ km and $B = 13$ km wide (elliptical shape, with $r = 0.65$). In the non-rotational case, the phase speed of the vertical mode-one seiche is $C = 0.25 \text{ ms}^{-1}$, and the period of the first horizontal longitudinal mode is $T_l = 2 \times 40 \text{ km} / 0.25 \text{ ms}^{-1} = 89$ h. Located at mid-latitude (44°N), $R_o = C/f = (0.25 \text{ ms}^{-1}) / (9.6 \times 10^{-5} \text{ s}^{-1}) \sim 2.6$ km and $S = R_o/R \sim 0.26$ (for the main basin, using

$R = L/2 = 10$ km) indicate that BSIWs will be affected by rotation. The longitudinal internal seiche becomes a Kelvin wave with period $T_l = 89$ h, and the transverse seiche, a Poincaré wave. Estimated for the main basin only, the period of the Poincaré wave is $T_{PW} \sim 16$ h for a rectangular basin (with $r = 0.65$ and $T_l \sim 2 \times 20 \text{ km} / 0.25 \text{ ms}^{-1} = 44$ h) but can be best estimated as an elliptical basin where $T_{PW} \sim 13.7$ h ($T_l/T_{PW} = 1 + 0.09S + 4.67S^2 - 0.346S^3$; see Antenucci and Imberger, 2001; their Table 1, with ratio 2:3).

The calculated wave periods are in good agreement with the observed 95-h and 14-h periods in Lake Simcoe (Figure 1), allowing the observed waves to be identified as Kelvin and Poincaré waves, respectively. Figure 4 shows the evolution of these waves over a wave period and highlights, in particular, the spatial and temporal variability associated with the BSIW – a nearshore Kelvin wave and a more offshore Poincaré wave. Given the circular nature of the lake, the waves shown are mode-one in the radial and azimuthal coordinate directions; higher horizontal modes in these directions are also possible (see Antenucci and Imberger, 2001; Wake et al., 2004).

Summary

Basin-scale internal waves are characterized by the basin shape, stratification, and the influence of the Earth's rotation. When the Burger number is large, $S > 1$, rotational effects are not important and the wind stress generates longitudinal and transverse internal seiches, as $S < 1$. These waves are gradually modified into Kelvin waves, traveling cyclonically with periods much longer than the inertial period, and Poincaré waves, traveling anticyclonically with periods close to, but lower than, the inertial period. In large lakes, $S \sim 0.01$ and the Kelvin wave becomes coastally trapped, while the Poincaré wave is confined to the basin interior.

BATHYMETRICAL SURVEY OF THE SCOTTISH FRESHWATER LOCHS, 1897–1909

Robert W. Duck
 School of the Environment, University of Dundee,
 Dundee, Scotland

Introduction

The *Bathymetrical Survey of the Scottish Fresh-Water Lochs* was carried out during the years 1897–1909 under the direction of Sir John Murray and, in the main, Lawrence Pullar. The six volume compilation (Murray and Pullar, 1910), comprising a grand total of 562 loch (lake) bathymetric maps, together with extensive

supporting biological, chemical, geological and physical information, represents an outstanding record of one of the most remarkable feats of field-based scientific endeavor of the late nineteenth and early twentieth centuries. No other country can boast such an important limnological archive; it remains today without equal and has renewed significance thanks to the requirements of the European Union (EU) Water Framework Directive (2000).

Canadian-born Murray (1841–1914), of Scottish parents, was educated at Stirling High School and the University of Edinburgh. He rose to fame as a pioneering oceanographer and marine biologist who played a pivotal role as assistant leader of the *Challenger* Expedition, which explored the deep oceans of the world from 1872 to 1876. He was subsequently responsible for editing and publishing over 50 volumes of expedition reports and was duly knighted in 1898. He returned to Scotland in the 1880s with the intention of undertaking nearshore oceanographic investigations around the coast. With the financial support of his good friend Lawrence Pullar, of Bridge of Allan, Stirlingshire, Murray built the 30 ton steam yacht *Medusa*, which from 1884 until 1891 was employed in the exploration of the nearshore waters around Scotland, including the deep glacially scoured sea lochs of the west coast (Duck, 1990). At this time, it became evident to Murray that virtually nothing was known of the depths of the innumerable fresh-water lochs of the country that formed such a significant scenic legacy of Pleistocene glaciation, especially in the Highlands. Naval officers had, in the interests of navigation, surveyed Lochs Lomond and Awe around 1860, and Murray himself had made a series of depth soundings along the long axis of the lochs connected to create the Caledonian Canal. However, this, along with some soundings in Lochs Katrine, Lomond, and Tay (Buchan, 1871), was the total knowledge of the bathymetry of the Scottish fresh-water lochs at that period.

Murray saw this as a huge gap in knowledge and proposed a systematic survey of the depths of Scotland's fresh-water lochs which he believed would, “in all likelihood result in many new additions to natural knowledge, and would be especially important for comparisons with results in other departments of scientific endeavour” (Murray, 1910). Many parties were interested in the depths of loch basins, such as geologists, in connection with their mode of formation (e.g., Wilson, 1888), fishermen and water supply engineers (Loch Katrine, for example, had become the principal water supply for the City of Glasgow in 1859). On Murray's initiation, the proposal was brought before the Councils of the Royal Societies of Edinburgh and London, both of which were in strong support and, in consequence, urged the British Government of the day in 1883 and 1884 to finance the surveys “in the interest of scientific progress” (Murray, 1910). Treasury support was not, however, forthcoming largely because of a lack of responsibility for inland bodies of standing water: the Scottish fresh-water lochs fell neither under the remit of the Admiralty, whose work was confined to the interests

of navigation, nor the Ordnance Survey, whose mapping operations were confined to dry land.

The Murray and Frederick Pullar Surveys

It is credit to Murray's determination and belief in the scientific merit of such a systematic survey that the idea was not allowed to die in 1884. However, it appears to have lain dormant for several years until it was reinvigorated with the keen enthusiasm of Frederick Pattison Pullar, son of Murray's good friend and benefactor Lawrence. Together Murray and Pullar, the younger, undertook to embark on bathymetric surveys at their own expense, thus commencing an operation that was initially regarded as a "holiday task" in 1897. By that year, however, knowledge of the depths of Scotland's fresh-water lochs had increased somewhat as, in the interim, four bathymetric surveys had been carried out by and officer of the Geological Survey of Scotland, J. S. Grant Wilson. In connection with his studies of the glaciation of the County of Perthshire, Wilson (1888) undertook soundings of the four so-called chief Perthshire lochs, namely, in order of decreasing surface area, Lochs Tay, Rannoch, Earn, and Tummel, for which he recorded maximum depths of 510, 420, 268, and 124 feet, respectively (c. 155, 128, 82, and 38 m, respectively). The results of this pioneering work, incorporating a small, colored, contoured bathymetric map of each water body, were published in the *Scottish Geographical Magazine* (Wilson, 1888). Little is known of Wilson's survey methods or the equipment he used, other than he took a series of depth soundings 50–80 yards apart (c. 46–73 m) along parallel traverses, from one side of a loch to the other (these are all relatively long, narrow, glacially scoured, rock basin lochs), spaced at intervals of about a quarter of a mile (c. 0.4 km). It is presumed that he must have used some form of weighted line; a steam-powered launch was employed to survey the largest body, Loch Tay, while for the other lochs, a rowing boat proved adequate.

Murray and Frederick Pullar commenced their formidable undertaking close to their Stirlingshire homes choosing to survey lochs in the drainage basin of the River Forth, in particular those of the Trossachs and Callander area of the southern Grampian Highlands. Three years later, by 1900, they had completed surveys of eight water bodies, Lochs Katrine, Arklet, Achray, Vennacher, Drunkie, Lubnaig, Voil and Doine for which colored, contoured charts were initially published in the *Scottish Geographical Magazine* (Murray and Pullar, 1900). One year later, in 1901, bathymetric charts of the remaining four major lochs of the Forth basin, Chon, Ard, Leven, and the Lake of Mentieth (Scotland's sole "lake"), together with two lochs of the neighboring Tay drainage basin, Ericht and Garry, were published in the same journal (Murray and Pullar, 1901a, b).

Prior to beginning their surveys proper, Murray and Frederick Pullar made many trial attempts to measure water depths using various devices. As none had proved entirely satisfactory, Pullar, who was of an inventive

nature (Chumley, 1901), designed and built what was subsequently to become known as the "F.P. Pullar Sounding Machine." This was mounted on the gunwale of a boat and comprised a drum around which was wound galvanized steel wire, which passed around a measuring pulley to a tubular weight. The system was such that for every foot (c. 0.3 m) of wire that ran out, the measuring pulley made one complete turn. The motion of the pulley was transmitted mechanically to a series of dials that indicated the length (in feet) of wire paid out in the water column. This ingenious piece of equipment was so successful and reliable that it was employed in all surveys except those in small, poorly accessible hill lochs in which graduated hand lines were used (Murray, 1910).

By the beginning of 1901, Murray and Frederick Pullar had completed a total of 14 loch surveys, and their target of countrywide coverage must have seemed long distant or even unattainable. In February of that year, tragedy struck; on the 15th of the month, Pullar lost his life at the age of 25. Along with many others, he was skating on Airthrey Loch, close to his Bridge of Allan home, when the ice cover gave way. Pullar helped three people to the shore but heroically drowned while trying to rescue a young woman who was suffering from exhaustion in the water. Onlookers claimed that, "he might easily have saved himself had he relinquished his burden: this he refused to do" (Murray, 1910). Murray, who had been out of the country for some months on a round-the-world voyage, arrived back in Britain to learn of his young friend's death the previous day (Chumley, 1901).

This tragedy brought the loch surveys to an immediate halt. Indeed, Murray (1910) wrote that it was his intention to abandon the project altogether. However, Murray's old friend Lawrence Pullar, Frederick's father, was convinced as to the scientific merit of the work and insisted that the surveys should continue as a memorial to his son. To expedite this, he generously donated £10,000 into a trust fund to provide the means to continue the project and took over his son's role as co-director. Such a sum would be equivalent to c. £850,000 today (2007).

The Murray and Lawrence Pullar Surveys

Now placed on a secure financial foundation, the loch surveys recommenced in the spring of 1902, a year after Frederick Pullar's death. The generous funding enabled the employment of a large team of scientific and technical personnel; 48 individuals took part, for longer or shorter periods, including biologists, geologists, physicists, zoologists, surveyors, boatmen and cartographers, as well as numerous boatmen and assistants employed temporarily in different parts of the country. By 1909, when the field operations were drawn to a close, an enormous total of 562 water bodies had been surveyed. "All lochs were surveyed," wrote Murray (1910), "on which boats could be found at the time the work was being carried out." This impressive total comprised not only the major, well-known, "iconic" Scottish lochs (such as Loch Ness and Loch Lomond) but also numerous smaller and less

familiar water bodies throughout the country, including several man-made water supply reservoirs (such as those of the Lomond Hills group, Fife), and many complex, shallow lochs in Shetland, Orkney and the Western Isles. In all, the surveyors recorded over 60,000 point “soundings” of water depth.

When measuring water depth, it is important that the position of the boat is established with accuracy. The Murray and Pullar surveys preceded the use of precision position fixing by techniques taken for granted today (e.g., GPS); they were conducted along traverses between known end points, typically prominent shoreline features such as deltas at the mouths of influent streams or buildings that provided a clear line of sight. Uniform spacing of soundings was accomplished by recording the water depth as quickly as possible so as to avoid boat drift after a fixed number of strokes (typically 10, 15, 20, or 50 according to the length of traverse) by the oarsman. In order to keep the boat on course when running lines of soundings, an aligning mirror was often used in the survey boat. By this means, an onshore feature behind the surveyor could be kept in line with a feature in front on the opposite bank.

During the period of the loch surveys, measurements of water temperature, movements (surface and internal seiches) and chemistry, loch biology and the character of the bottom sediments were also carried out. The bathymetric maps themselves are masterpieces of cartography, prepared and color lithographed by J. G. Bartholomew & Son of Edinburgh at a scale of 3 in. to 1 mile (1: 21,120). The depth soundings were contoured at regular intervals, each division being colored in a shade of blue, becoming progressively darker with increasing depth. Around half of the 233 plates that comprise the 562 individual maps also show the topography shaded with darkening shades of brown indicating progressively higher relief. The later maps in the series (those of Murray and Pullar, 1910, Vols. 5 and 6) show only the blue colorations of water depth. The maps, together with a descriptive account of each loch, chapters on the associated scientific observations and tables of statistics relating to the suite of water bodies (length, surface area, maximum depth, mean depth, volume; the interrelationships between which have been evaluated by Gorham, 1958), were collated into six volumes and published by the Challenger Office, Edinburgh (Murray and Pullar, 1910). At the time the six volume set, representing around 12 years of fieldwork, retailed at five guineas (£5.5 s.d = £5.25p). Today, the maps have been made available free of charge on the Internet by the National Library of Scotland (<http://www.nls.uk/maps/early/bathymetric/>).

The deepest sounding measured in all of the c. 60,000 of the 562 surveys was of 1, 017 ft (309.98 m) in Loch Morar. The second deepest was found to be Loch Ness (maximum 754 ft, 229.82 m), followed by Loch Lomond (632 ft, 192.63 m), Loch Lochy (531 ft, 161.85 m), Loch Eriach (512 ft, 156.06 m), Loch Tay (508 ft, 154.84 m),

Loch Katrine (495 ft, 150.88 m) and Loch Rannoch (440 ft, 134.11 m). In his introduction to the six volumes, Murray (1910) reflected that, “It was rather amusing at times to observe the result of the soundings on the inhabitants of districts in which the lochs are situated. As a rule, lochs, or some parts of a loch, are regarded as very deep or without bottom. When a loch with this reputation was found to be relatively shallow, the result would be questioned, and a feeling of affront or injury prevailed among the inhabitants of the district.”

Significance of the “Murray and Pullar” Surveys Today

In the intervening century since the “Murray and Pullar” surveys were completed, the character of Scotland’s lochs has changed considerably, not least in the Highlands. The advent of hydroelectric power generation following World War II has resulted in the construction of large numbers of mass concrete, buttress and arch dams. In some valleys, these have created new lochs (e.g., Loch Faskally, Loch Errochty), whereas at other sites, dams have raised the water levels, and thereby the surface areas, of existing lochs (e.g., Loch Tummel, Loch Garry). Natural sediment influx and, in places, increased rates associated with land use changes have continued to contribute to delta growth at the mouths of influent rivers and streams and to offshore loch floor deposition. The Murray and Pullar surveys thus represent important baselines from which to evaluate such changes in hydromorphology a century or so later.

Where re-surveys of water bodies have been undertaken with modern methods of sounding and position fixing (e.g., Duck and McManus, 1985; Duck, 1986; Lowe et al., 1991a, b; Young and Shine, 1993) and the bathymetric data can be directly compared with those of Murray and Pullar, the differences serve to emphasize the accuracy of the latter. While modern methods may reveal deeper hollows that the original surveyors missed using point soundings, the overall morphology of the basins was accurately captured using what today are regarded as relatively primitive surveying techniques.

In recent years, the Murray and Pullar surveys have assumed an even greater significance due to The EU Water Framework Directive (WFD), which was introduced in 2000 to establish a new legal framework for the protection, improvement and sustainable use of all water bodies, including lakes, across the European Union. The Directive stipulates that surface water bodies, such as lakes, should achieve good ecological and chemical status by 2015. Implementation of the WFD presents a series of challenges to EU member states, one of which concerns the lack of adequate baseline data, such as lake bathymetry. For example, Great Britain (England, Wales and Scotland) has over 40,000 lakes >1 ha in surface area (and thus covered by the WFD), but bathymetric data are available for less than 2% (Rowan et al., 2006). Morphometric data, for example lake volume, derived from bathymetric surveys, are necessary for the calculation of important parameters such as basin residence time. The requirement for

good quality bathymetric data is essential for lake management and for the effective compliance of the WFD. When such data are not available, it is necessary to make estimates based on empirically derived relationships from map-derived parameters and predictive models that derive from actual bathymetric data (Rowan et al., 2006). The 562 Murray and Pullar surveys from Scotland, even though they actually cover only a small fraction of the lochs in the country, represent over 90% of the currently available bathymetric data for lakes in Great Britain. They are thus of prime importance as input data to such predictive models, that vary according to lake typology, and collectively place Scotland at an advantage for WFD implementation in terms of the quality and quantity of its baseline lake bathymetric data.

BEAVER DAMS AND PONDS

Jean-Marie M. Dubois, Léo Provencher
Département de Géomatique Appliquée et CARTEL,
Université de Sherbrooke, Sherbrooke, QC, Canada

Introduction

Like the human being, the Canadian beaver is the only animal creating its own habitat by modifying the biophysical environment. The result of this modification is the creation of a lake environment along streams or ditches. Beaver is sometimes named “the engineer of Nature”. Its name seems to come from the Sanskrit word *kasturi*, which means *musk*, because the castoreum used in perfumery is known by Indo-Europeans since antiquity (Anonymous, 2006).

Beavers distribution

Three species of beaver exist. The first one, the Mountain beaver (*Aplodontia rufa*), is living in the Rockies along the Pacific coast of North America, from California (USA) to southern British Columbia (Canada) (Banfield, 1974). The second one, the European beaver (*Castor fiber* L.), was living on almost all the European territory before the XVIIth century. Now, it is mainly living in Russia, Scandinavia, Bielorussia, and Baltic countries. But it is scattered in other European countries except Italy, Iberian Peninsula, south of Balkan Peninsula, and Caucasus where it is absent (Manet and Fichet, 2004). The last one, the Canadian (or American) beaver (*Castor canadensis* Kuhl), is living on almost all the territory of Canada and USA as far as the northern limit of trees (Banfield, 1974). The Canadian beaver has been introduced in Finland in 1937, Tierra del Fuego (Chile) in 1948, USSR in 1950, and France in 1970 (Prescott and Richard, 1996).

Beaver characteristics and habits

The Mountain beaver has not the anatomic characteristics of the Canadian beaver and then is not a true beaver. It is a rodent that must be compared to a muskrat without a tail and living in burrows along streams. The Mountain beaver sometimes builds little dams with vegetation debris and mud (Banfield, 1974).

The European beaver has the anatomic characteristics of the Canadian beaver but weighs less than 30 kg. It has no interest in dam construction and confines its efforts in digging burrows into the stream banks (Prescott and Richard, 1996).

The Canadian beaver is the biggest rodent of North America and the second biggest that exists in the World. The biggest is capybara of South America (*Hydrochaeris hydrochaeris*). The Canadian beaver may weigh up to 35 kg (Banfield, 1974) or even 45 kg (Prescott and Richard, 1996). Its large webbed back feet serve as oars and its flat tail is covered with scales and serves as a rudder when swimming, as a support when cutting off

trees, and as a lever, but not as a trowel. Beaver has long and sharp incisors serving to cut trees as large as 40 cm. Beaver has more ability in swimming than in walking. The yearly average beaver litter is two young, living with their parents for 2 years. Afterward, the young beavers are driven out of the colony by their parents and have to create new colonies. It is the female that selects the site of the colony. As the beaver does not hibernate, it must constitute a viable and safe environment for the winter time.

Construction of the habitat

When a beaver colony is settling, beavers begin by erecting a watertight dam across a small stream or ditch. They choose a site with a soft substrate and in an environment where there are enough deciduous trees for at least a year (Banfield, 1974). Beavers usually settle down along a stream of low flow without important fluctuations, with a longitudinal slope of less than 3–6% and a watershed of less than 15 km² (Comeau, 2006). The dam is made of poles, branches, roots, pieces of rocks, turfs, and mud (Figure 1). The dam is anchored in the substrate with poles and branches set up parallel to the current and with the tips oriented upstream. Other materials are placed across and tamped by water flow. The dam is widened and heightened by piling successive layers of sticks and debris. As the water level rises, beavers lengthen the dam at both ends. The dam must be high enough to create a pond of about 2–3 m deep to allow the beavers to swim under an ice cover that can reach a thickness of about 1 m. The overflow is always located in the central part of the water bed where the flow is the highest. The dams can reach a height and a thickness at the base of 2–3 m and a length varying between a few meters to about 200 m. Mills (1913) reports a 650-m-long dam in Montana. Beavers can also build secondary upstream dams to protect stockpiles of food (food caches) and downstream dams to help in sustaining the main dam by creating a water counterpressure

Beaver Dams and Ponds, Figure 1 Beaver dam on Anticosti Island (Québec, Canada). (Photo: Dubois, J. -M. n° 82-5-26.)

at its base. The flooding of the forested land causes the death of numerous trees on a surface larger than the pond itself.

The dam protects the lodge built by the beavers with the same materials as the dam. The lodge is located at the center or on the side of the pond. The lodge is round, conical, and usually measures between 2 and 3 m high and between 3.5 and 7 m in diameter (Figure 2). The accesses are submerged to baffle the predators, and ramps give access to the emerged inner chamber. The beaver gets its materials by cutting trees and can even build small channels to float the logs toward the pond. The dam maintains a constant water level to protect the lodge and to get access to the food.

The main source of food is the cambium of deciduous trees, including leaves, buds, and twigs. The main species are Trembling aspen (*Populus tremuloides*) Willows (*Salix* sp.), Alder (*Alnus* sp.), White Birch (*Betula papyrifera*), Mountain-ash (*Sorbus* sp.), Cherry tree (*Prunus* sp.), and Maple (*Acer* sp.). Sometimes, mainly in northern regions, beavers also eat the cambium of

Beaver Dams and Ponds, Figure 2 Beaver lodge in a pond center in Rivière-des-Mille-Îles Park (Laval, Québec, Canada). (Photo: Leblond, M., Parc de la Rivière-des-Mille-Îles, *Le Monde en images*, Collège de Maisonneuve, Montréal, n 15226: <http://www.ccdmd.qc.ca/>)

coniferous trees. An additional source of food is aquatic plants and rhizomes. The pond allows the growth of a diversity of such plants and increases their biomass. The beaver maintains one or several underwater stockpiles of food nearby its lodge for winter time. A wood supply is always necessary to repair the dam and the lodge. When that wood supply is worn out after 2 or 3 years, the colony moves to another site. Some colonies, mainly in Europe, do not build lodges but live in burrows into the stream banks with underwater accesses. There are 2–14 members for each colony with an average of 4. Beavers stay close to the stream banks and their area of cutting down trees. The width of these areas can reach 150 m.

The surface of the ponds (lakelet) can be as little as few tens of square meters but can sometimes reach 1 square kilometer. A survey by airphoto interpretation with terrain validation in the Kouchibouguac Canada National Park in New Brunswick shows that beavers have inundated a surface of about 3 km² of the 293 km² of the park surface (Figure 3). The 138 beaver colonies within the limits of the park have built 152 ponds with a mean surface of 2 ha (Dubois et al., 1997). Some colonies have built as much as six dams of 0.5–1.5 m high and of 4–200 m length. Some ponds had a surface as little as 0.03 ha while others could reach over 30 ha (Boucher et al., 1997). All the colonies were not active because 35% had no evidences of beaver activities. These evidences have been recognized and summarized by several research projects (Dubois, 1982; Labrie and Dubois, 1988; Labrie et al., 1992; Dubois et al., 1997; Boucher et al., 1997): high water level pond, well-maintained dam and lodge (conical shape) indicated by fresh mud, fallen trees close to the banks of the pond or the stream, floating channel that may reach several tens of meters in length, and underwater stockpiles of food (only in autumn).

Impacts on the environment

The first impact related to beaver activities is the modification of a part of a watercourse into a lake environment. Trees, bushes, and grass of the inundated areas rapidly die, but tree stumps can stand up for many decades. This terrestrial vegetation is rapidly replaced by aquatic vegetation. In drained out ponds abandoned by beavers, the regeneration of the trees can take as much time.

Ponds have also an impact on the fluvial dynamics. Ponds give rise to the deposition of sediments due to the reduction of the water speed flow entering the pond. The importance in the deposition of sediments in the ponds is correlated to the quantity of sediments carried out by the fluvial system and the duration of the pond. In some extreme situations, the watercourse can change place when a breach opens into one of the lateral parts of the dam.

Dams have an impact on the stream fish habitat. They hold up the fish circulation and cause the rise of the water temperature which can be prejudicial for some salmonids.

Beavers also have an impact on the human being infrastructures. They can obstruct channels or culverts flooding

Beaver Dams and Ponds, Figure 3 Beaver pond landscapes in Kouchibouguac Canada National Park: (a) chain of ponds on a little stream; (b) big pond with a long dam built by the beavers; (c) big pond dammed by a road dike after the obstruction of a culvert by beavers. (Photos: Government of Canada n A31533-49 and 173.)

roads, railroads, seasonal recreation places, cultivated lands, and valuable woodlands. On Anticosti Island in the northern part of the St. Lawrence Gulf (Québec), beavers have been seen constructing a dam obstructing ditches on both sides of a road and the road itself, thus flooding the road on several 100 m. In all these situations, beavers must be captured and relocated in places similar to the original site (Dubois et al., 1997).

On the other hand, beaver ponds can have a positive effect. Indeed they help to reduce the spring flood peak discharge of watercourses reducing the erosion risks. They also create an aquatic habitat similar to a freshwater swamp, which attracts a diversified fauna of fishes, waterfowl, amphibians, reptiles, and small and great mammals.

Introduction

The Bengal Basin is one of the most extensive sediment reservoirs in the world and constitutes the lower flood-plain and delta plain deposits of India and Bangladesh, at the mouth of the Ganga–Brahmaputra–Meghna River systems. The delta formation initiated at ~11 ka when the sea level rose to trap the riverine, fluvio-deltaic to overlying estuarine and mangrove-mud-containing shells;

wood; and organic debris (Umitsu, 1993; Goodbred, 2003). The most notable sediment discharge took place during ~11–7 ka when the sediment flux in the Ganga–Brahmaputra delta was at least 2.3 times higher than the present. The Ganga–Brahmaputra River systems together carry the world's largest sediment load, 80% of which is delivered during the four monsoon months (Goodbred and Kuehl, 2000). As a consequence, the Bengal Basin acts as a huge sediment sink with wide dispersal systems often related to a wide range of climate change.

Goodbred (2003) suggested that the deposits of Bengal Basin have responded to multi-millennial scale climate change all through the time of their deposition across the huge basin. Chauhan et al. (2004) have identified between 11 ka and 9.5 ka, two major phases of fluvial influx in the Bengal Basin. Lithostratigraphic and geochronologic studies from bore-hole samples have established the Late Quaternary (the latest Pleistocene and Holocene) succession of the Bengal Basin consisting mainly of sand, silt, and clay with a few distinctive beds useful for correlating stratigraphic units (Banerjee and Sen, 1987; Hait et al., 1996; Goodbred and Kuehl, 2000). There has been variation in physical and chemical weathering processes in the sedimentary sequences with change in climatic condition. The Late Quaternary sediments of Bengal Basin have shown high concentration of smectite and kaolinite during ~10–7 ka, indicating enhanced chemical weathering under warmer and more humid conditions (Heroy et al., 2003).

Bengal basin boundary

Bengal Basin (lat 21° N to 26° N and long 87° E to 92° E) is the foreland basin of the Eastern Himalayan Range. The basinal area occupies the subaerial and subaqueous deltaic deposits of the Ganga–Brahmaputra Rivers covering parts of northeast India and almost the whole of Bangladesh. The north and northeast boundaries of the basin are delineated by the east–west extending Shillong Massif separated by the Dauki Fault. The eastern side of the basin is bounded by the north–south extending uplifted fold belt, the Tripura Fold Belt (i.e., the Indo-Burma collision boundary). The northwestern boundary of the basin is delineated by the basaltic traps of Rajmahal Hills. Further south–southwest of the basic trap deposits lies the gneissic complex of the Archean Shield. The acidic Archean rocks disappear below the veneer of the older and recent alluvium between lat 87° E and 88° E. Patches of coal-bearing Gondwana sedimentaries and undifferentiated Tertiary rocks unconformably overlie the Archean gneissic terrain at the contact of the Pleistocene and recent alluvium (Figure 1).

Tectonic setting

The Bengal Basin is tectonically active in both space and time and is tectonically highly disturbed by earthquakes, folding, faulting, and other neotectonic movements. All these have direct impact in controlling the geomorphic

Bengal Basin, Sediment Sink, Figure 1 Geological map of the Bengal Basin.

and sedimentary features like the patterns of river courses, shifting and avulsion of rivers, sedimentary facies, and sediment dispersal patterns. The basin margin in the west is marked by a number of subsurface ridges and depressions followed by a series of en echelon faults further east. The stable shelf of the basin in the west very gently dips to the southeast to attain its maximum depth in Bangladesh. The basin bottom deepens with the Archean basement complex overlain by the basaltic flows. The edge of the shelf is characterized by a northeast–southwest trending subsurface “hinge zone” – a zone of subsurface flexure (Figure 1) on the overlying Eocene limestone horizon. The flexure has been recorded at a depth of about 4,725 m below Kolkata and has been supposed to be responsible for the tectonic movement at the shelf–slope break. The regional southerly slope of the Bengal Basin along with eastward migration of the Ganga over the Holocene also owes its origin, at least partly, to the movement on the hinge zone. An increasing rate of southerly tilt of the Indian part of the basin is also noticed due to relatively greater rate of subsidence of the southwestern part of the hinge through the Tertiary and Recent times (Sengupta, 1972).

The northern part of the Bay of Bengal constitutes the southern limit of the Bengal Basin. The basin has been gradually closing because of the oblique eastward subduction beneath the Tripura Fold Belt (Indo-Burman Range) and the Sunda Outer Arc. These plate-driven tectonic processes have been responsible in generating the subsidence rate of the basin up to 4 mm/year (Goodbred and Kuehl, 2000). The compressional stress from the north causing upliftments in various parts of the basin comes from the overthrust block of the Shillong Massif. The eastern part of the Bengal Basin is tectonically more complex compared to the southern part where the delta front is less active tectonically. The 1782 earthquake caused avulsion of the course of the old Brahmaputra River. The uplifts and subsidence at several places altered the accommodation space, rate of sediment delivery, river channel widening and constrictions, and sediment dispersal.

Vertical displacement of sedimentary sequences is evidenced from a number of places in the basin. The Madhupur Terrace and the Barrind Tract are uplifted (>10 m) alluvium deposits of Pleistocene age (Morgan and McIntire, 1959). The eastern part of the basin as far as the Madhupur Terrace is affected by the shortening of the accretionary wedge of the Tripura Fold Belt (Indo-Burman Fold Belt). The Madhupur Terrace is located in the SSW of Shillong Massif, whereas the Barind Tract is in its northeast. Evidence of Holocene neotectonic upliftments (5–10 m) is noticed from three areas within the basin. These include (1) Mymensigh Terrace situated along the course of the old Brahmaputra River in the north of the Madhupur Terrace, (2) the Komilla Terrace in the east of the basin in the contact of the Tripura Fold Belt, and (3) around Kolkata (Samad and Khandoker, 1984). Many of the tectonic movements, imprints of which were recorded from sediment accumulation history in the

basin, were influenced by isostatic loading, subsidence, overthrust, and compressional forces.

In contrast to the areas of upliftments, there are two peludal sub-basins (<3 m deep) within the Bengal Basin. These are the Sylhet Basin in the south of the Shillong Massif and the Atrai Basin in the south of the Barind Tract (Figure 1). The Sylhet Basin, a foreland trough, is formed due to overthrusting of the Shillong Massif (Alam, 1996; Goodbred and Kuehl, 1999). The subsidence rate in the basin has been determined to vary from 1 to 3 mm/year. Differential rates of compaction of sediments and/or tectonically induced subsidence characterize these intrabasinal areas.

Bengal basin as a sink of sedimentation

The Bengal Basin has captured the Ganga–Brahmaputra River systems at their downstream stretches. The two rivers have coalesced in the Bengal Basin about 150 km upstream of the present land–sea interface. The combined sediment load of the two rivers to the tune of 10^9 t/year had led the basin to be identified as one of the world’s largest depocenters. The Bengal Basin is comprised of about 100,000 km² of lowland floodplain and delta plain areas. The Ganga alone discharges 520×10^6 t of annual sediment load, 95% of which is delivered during the four wet monsoon months (June–September) of the year (Goodbred, 2003). From north to south, the Ganga–Brahmaputra delta has two portions, a subaerial delta and a subaqueous delta. The subaerial delta has an upper river floodplain followed southward by the deltaic plain with many distinctively different geomorphic zones like the Sundarban mangrove swamps, estuaries, intertidal mudflats, and beach-ridge complex. The high-resolution seismic studies have definitely established the Holocene evolution of the subaqueous counterpart with a typical clinoform structure (Kuehl et al., 1997). This subaqueous delta started to form on the Bengal shelf since about 7,000 years B.P. with a sediment fill rate of 0.42×10^9 t/year and yielding a fill volume of $1,970 \times 10^9$ m³ (Kuehl et al., 1997). Estimation of this volume has revealed that the subaerial delta holds 30%, and the subaqueous delta holds 40% of the Holocene sediment load of the rivers; the remaining 30% is supposed to reach the submarine canyon “Swath of No Ground” and the deep sea Bengal fan. The growth of the subaqueous delta with active accumulation of sediments in the clinoform morphology also explains the apparent insignificant progradation of the present-day shoreline (Coleman, 1969). Although the Bengal Basin is the primary sink of sediments of the Ganga–Brahmaputra Rivers, the deep sea Bengal fan also serves as the ultimate sink for these Himalayan Rivers (Curry and Moore, 1971; Bhattacharya, 1999).

The depositional history of the Bengal Basin initiated with the deposition of the clastic rocks of Cretaceous–Palaeocene age (Figure 2). Thin lenticular shale/claystone units were deposited on the southeasterly sloping Archean basement complex with basaltic traps. These rock units

Bengal Basin, Sediment Sink, Figure 2 Cross section across the Bengal Basin to show subsurface configuration in Lithofacies (After Sengupta, 1972).

were overlain by the Eocene Nummulitic Limestone over the same southeasterly sloping underlying units on the western part of the Bengal Basin margin of West Bengal (India). The overlying thick Oligo-Miocene to Pliocene clay/claystone and sand/sandstone units constitute the bulk of the early-phase deposition of the Bengal Basin that reaches up to a depth of over 14,000 m in Bangladesh. The latest Pleistocene and Holocene sedimentation in the Bengal Basin had been divided into five units by Umitsu (1993). The lowest unit is characterized by gravels and formed at the maximum epoch of the last glacial ice age when level in this area increased rapidly. The immediately overlying unit is made of sand and gravel of age 12,000 year B.P. The middle unit is sandy and is formed during Middle Holocene when the coastline retreated southward, whereas the upper two units are made of sand, silt, and clay with intercalated peats at places. The uppermost Late Holocene transgressive unit is chiefly composed of silt and clay with intercalated peat layers. The radiocarbon-dated cores taken at places helped subsurface mapping and delineation of Holocene deltaic sequences and underlying transgressive units of Late Pleistocene alluvial deposits of the Bengal Basin, particularly in the western part (Stanley and Hait, 2000). The vast portion of the modern top stratum tidal deposits with various sub-environments in the Bengal Basin is characterized by numerous tidal and wave-generated bedforms and biogenic structures (Bhattacharya, 1999, 2001). There has been an interfingering of fluvial, fluvio-tidal, and tidal sedimentary facies in the basin across shoreline from the landward to the seaward direction.

Present status

Being positioned at the mouths of Ganga, Brahmaputra, and Meghna Rivers along the northern boundary of the Bay of Bengal, the subaerial part of Bengal Basin is a “bread basket” for a high-density population of India and Bangladesh. In addition to the natural forcing imparted by periodic cyclones and wave surges, anthropogenic stresses causing influx of organic and inorganic pollutants in the sediments have become a matter of great concern for the last few decades (Chatterjee et al., 2007;

Binelli et al., 2007). Recent estimate reveals that out of over 235 million population in the Bengal Basin and its adjacent areas, about 80 million people are facing a serious environmental stress from the toxic poisoning of arsenic in ground water. Both the natural setting and anthropogenic activities are supposed to be responsible for the arsenic toxicity (Acharyya et al., 2000).

BROWNIFICATION OF LAKES

Wilhelm Graneli
Aquatic Ecology, Department of Biology, Lund
University, Lund, Sweden

Synonyms

Browning

Definition

Brownification signifies an increase in the yellow-brown color of lake and stream water, caused mainly by dissolved humic matter of terrestrial and wetland origin, which absorbs solar radiation strongly in the short wavelength part of the visible spectrum.

Long-term changes in water color - causes and consequences

Many streams and lakes, from temperate to tropical climate zones, contain high concentrations of dissolved organic matter (DOM). There are two main sources of DOM in inland waters: internal production via plankton and aquatic macrophytes, and external inputs of DOM of terrestrial or wetland origin. Terrestrially derived DOM often dominates in freshwaters, and if concentrations are high (e.g., DOC – dissolved organic carbon – above 10 ppm in a nutrient-poor lake), the water is usually visibly brown-colored (Figure 1). Lakes with brown-colored water are called dystrophic or polyhumic. Terrestrial and wetland DOM is composed largely of high molecular weight residues (humic matter) of microbially processed plant detritus, leached from the soil profile. The (humic) color of water has traditionally been measured using a platinum salt solution as reference, thus lake color is given as mg Pt/l. This color scale has today been substituted by measurements of absorbance, at wavelengths around 400 nm. The DOM concentration and color of lake and stream water show both seasonal and year-to-year fluctuations, as well as long-term trends (Pace and Cole, 2002). Over the last decades, there has been a marked “brownification” (or browning (Roulet and Moore, 2006)) of a large number of running waters and lakes in NW Europe and in N America (Forsberg, 1992; Hongve et al., 2004; Evans et al., 2005; Roulet and Moore, 2006; Vuorenmaa et al., 2006). Color has in several cases more than doubled in a few decades (Figure 2). DOC has also increased, although often not as much as color. Brownification may thus be caused both by changes in the quantity and in the quality of terrestrially derived DOM. An increase in the iron content of surface water may also cause brownification. Brownification has been attributed to decreased

Brownification of Lakes, Figure 1 Brown-colored lake, the province of Småland, south Sweden. Photo W. Graneli 2007.

Brownification of Lakes, Figure 2 Color (as absorbance at 420 nm of filtered water) of River Helge at Lake Hammar, Scania, south Sweden. Data from national monitoring (<http://webstar.vatten.slu.se/db.html>).

atmospheric sulfur deposition (reversed acidification, Monteith et al., 2007), climate change, e.g., increased precipitation/runoff (Hongve et al., 2004; Erlandsson et al., 2008) and higher temperatures (Weyhenmeyer and Karlsson, 2009) and changes in land use, as well as combinations of these. Although most of the proposed potential drivers of brownification are connected to human influences, natural fluctuations, especially in climate, could also be involved. If brownification is an effect of wetter and warmer conditions and/or changes in land use (reduced cultivated area, more coniferous forests), a continued brownification could be expected in coming decades. However, if climate change causes reduced precipitation and run-off, lakes may on the contrary become less colored. If reversed acidification, due to greatly reduced emissions of acidifying sulfur oxides since the 1970s is the cause, brownification is a return to pre-acidification conditions, and the process will level off. Paleolimnological evidence suggest that lakes in south Sweden were as brown as today or even browner 100 years ago, supporting the reversed acidification hypothesis (Cunningham et al., 2011). Monitoring data and experimental acidification of soils also support this hypothesis (Monteith et al., 2007; Ekström et al., 2011). Brown coloring DOM has profound effects on lake ecosystems, organism communities, and on human use of lakes and lake water. Brownification affects lake ecosystems by drastically reducing the penetration of solar radiation into the water column, which causes a decrease in lake ecosystem primary production, as well as secondary production, e.g., of benthic invertebrates and fish (Karlsson et al., 2009). On the other hand, brownification increases organic carbon available for bacterial growth, intensifying oxygen consumption and CO₂ production. Although there are some positive effects, e.g., increased UV-protection of organisms, brownification has mostly negative consequences from a human perspective. Among these can be

mentioned: more costly treatment procedures for drinking water, reduced aesthetic value for water sports, reduced biodiversity, and reduced fish production (Karlsson et al., 2009). Lakes and streams are globally significant conduits for the transfer of CO₂ to the atmosphere (Tranvik et al., 2009), and brownification will cause increased CO₂ emissions to the atmosphere from freshwater ecosystems (net heterotrophy), due to intensified microbial processing of DOM in lakes and running waters.

Summary

Brownification is the process whereby the brown color of stream and lake water increases. Brown color of freshwater is caused by strong absorption of short wavelength visible solar radiation by dissolved organic matter, possibly in combination with iron, leached from soils in the catchment. Brownification is probably an effect from greatly reduced anthropogenic sulfur emissions during the last 30–40 years, increasing soil and surface water pH and mobilizing DOM bound to the soil under more acid conditions. However, there is no consensus among scientists with respect to the driver(s) behind brownification. There are also alternative or complementary explanations: climate change (especially increased precipitation and temperature) and land-use changes. Paleolimnological studies indicate that lakes in southern Sweden were even browner 100 years ago compared to today. Brownification has mainly negative effects on human use of freshwaters.

C

CARBON CYCLE IN LAKES

Amy Myrbo

Department of Earth Sciences, LacCore/Limnological Research Center, University of Minnesota, Minneapolis, MN, USA

Introduction

The lacustrine carbon cycle involves the interactions of gaseous, dissolved, and solid forms of C. Inputs include carbon derived from the atmosphere, surface water, groundwater, regolith, and bedrock. Transformations within the lake system include biotic and abiotic processes occurring in both the presence and absence of oxygen. Losses occur to the atmosphere, to streams and groundwater, and to the sediment underlying the water (Figure 1). Many lacustrine processes have familiar counterparts in marine systems. Lakes are not small oceans however; important aspects of the carbon cycle such as the relationship between dissolved gases and the atmosphere, and the role of organisms in carbonate mineral formation, differ strikingly in lakes as compared with the ocean. Lakes are strongly influenced by processes occurring in their catchments, because of the high ratio of shoreline to open water, while the oceans are affected only locally by continental processes. Large lakes such as the Laurentian and East African Great Lakes behave more like oceans than like small lakes; however, their water chemistries differ significantly from typical ocean chemistry and from one another. Lakes process a tremendous amount of carbon, given their small collective areal extent, sequestering organic and inorganic carbon in their sediments as well as emitting large quantities of carbon dioxide and methane to the atmosphere.

Density stratification of lakes plays a major role in carbon cycling. The differentiation of the cold, dark,

stagnant hypolimnion from the warmer mixed epilimnion, part or all of which may be within the photic zone, promotes different biological and chemical processes in the two layers. Photosynthesis, wind mixing, and atmospheric exchange lead to higher pH and dissolved oxygen saturation (or supersaturation) in the epilimnion, while the hypolimnion, isolated from the atmosphere and receiving sinking organic matter, may evolve toward anoxia, carbon dioxide supersaturation, and low pH due to respiration.

Lake water chemistry is highly variable, ranging from almost pure rainwater in lakes with small catchments on crystalline bedrock, to several times the salinity of seawater, and from low to high pH (~3–11). The ionic composition of lake water is a reflection of the surrounding geology and is further affected by climatic factors such as precipitation-evaporation balance. Major ions in surface water may include virtually any combination of K^+ , Na^+ , Mg^{2+} , Ca^{2+} , HCO_3^- , CO_3^{2-} , SO_4^{2-} , Cl^- ; under reducing conditions in anoxic bottom waters, dissolved Fe^{2+} and Mn^{2+} may also be major. Lakes with sufficient alkalinity may precipitate carbonate minerals, similar to the formation of limestone in the oceans; these are sometimes termed “hardwater” lakes, and in these lakes carbonate geochemistry represents an important part of the C cycle.

C reservoirs and fluxes in lakes

Lakes and the atmosphere

Lake surface waters are typically out of equilibrium with respect to atmospheric carbon dioxide (Cole et al., 1994). This finding might be expected for periods of the summer when high rates of algal photosynthesis draw down dissolved CO_2 below atmospheric equilibrium values; however, many lakes surveyed are actually well above CO_2 saturation. Supersaturation occurs because of the influence of the catchment on lake water chemistry.

Carbon Cycle in Lakes, Figure 1 Schematic diagram of the major carbon cycle processes in hardwater (carbonate mineral producing) lakes. Softwater lakes with lower pH and DIC (see text) lack the carbonate ion and carbonate mineral (CaCO_3 s) portions of the cycle but are otherwise comparable. DOC is excluded from the diagram for simplicity; it acts as an organic matter source for a number of microbial and abiotic processes.

Particulate and dissolved C-bearing materials enter the lake via surface and groundwater and overland flow, and are processed (decomposed, dissolved, etc.) there, releasing CO_2 into the lake water. The diffusion of gases across the air-water interface is relatively slow, allowing the lake water to exceed CO_2 saturation. Evasion of CO_2 and of methane (see below) to the atmosphere can occur both by diffusion and by ebullition (bubbling out).

Dissolved inorganic carbon and the carbonate system

Dissolved carbon dioxide is hydrated to the uncharged species $\text{H}_2\text{CO}_3^\circ$ (carbonic acid), which rapidly dissociates into HCO_3^- (bicarbonate ion), CO_3^{2-} (carbonate ion), and protons. The relative abundance of these dissolved species (when including dissolved CO_2 and $\text{H}_2\text{CO}_3^\circ$, collectively termed “dissolved inorganic carbon,” DIC, or “total inorganic carbon,” TIC) depends on the pH of the water, with $\text{H}_2\text{CO}_3^\circ = \text{HCO}_3^{2-}$ (and CO_3 negligible) at pH=6.35 and $\text{HCO}_3 = \text{CO}_3^{2-}$ (and H_2CO_3 negligible) at pH=10.33. Some algae and higher plants can use HCO_3^- as well as CO_2 in photosynthesis. Carbonate ion reacts with a cation such as Ca^{2+} or (less commonly) Mg^{2+} , Na^+ , Fe^{2+} , or Mn^{2+} to form carbonate minerals such as calcite (CaCO_3). Calcite often precipitates abruptly and massively in events known as *whittings* (e.g., Hodell et al., 1998). These events, as well as more steady carbonate

precipitation, are triggered by a combination of factors that increase calcite saturation and all occur during early to mid-summer: rising water temperature (carbonate solubility decreases with increasing temperature), photosynthetic drawdown of CO_2 (increasing pH and driving the carbonate equilibria toward CO_3^{2-}), and evaporation (increasing the concentration of Ca^{2+} and CO_3^{2-}). Algae in the water column also act as nucleation points for the precipitation of minerals and generate aqueous microenvironments far exceeding carbonate saturation. With the exception of the green alga *Phacotus*, which forms a calcite lorica, and pelagic ostracodes, which have calcified valves, all carbonate minerals formed in the pelagic zone of lakes are abiogenic (though biologically mediated; Kelts, 1978). Lacustrine carbonate minerals thus stand in sharp contrast to those found in oceans, where virtually all carbonate occurs as the tests of organisms such as foraminifera and coccolithophorids. The shells of ostracodes and molluscs can be important components of the littoral sediment in lakes as well.

Dissolved organic carbon

Myriad biogeochemically important but poorly characterized molecules comprise the suite of compounds known collectively as dissolved organic carbon (DOC). DOC is divided into classes based on chemical separation techniques or molecular masses. While some DOC molecules

are recalcitrant (and thus persisting in aquatic environments without further decomposition), some DOC compounds that are stable in soils or groundwater may be subject to photolysis when they enter the light environment of lakes, and can also be utilized by aquatic microbes. Respired DOC is thus a significant contributor to the CO₂ supersaturation of lakes described above (e.g., Cole et al., 2002). DOC may be a relatively small fraction of the lacustrine carbon pool in hardwater systems, but is by far the largest pool in some softwater lakes.

Photosynthesis and respiration

Green algae (chlorophytes) and diatoms (bacillariophytes) are ubiquitous photosynthetic organisms in pelagic zone in lakes. They convert CO₂ (and in some cases HCO₃⁻, as noted above) into biomass. Their relative abundance is affected by windiness (diatoms' silica frustules are denser than water and so they require turbulent water to stay in the photic zone), nutrient abundance (N, P, Si, and others; most lakes are considered to be P-limited), and turbidity. In some lakes, especially those with high dissolved P levels, these algae may be replaced in middle or late summer, when dissolved N is depleted, by cyanobacteria (blue-green algae) that can fix nitrogen from the atmosphere and thus can capitalize on the remaining available P. Some cyanophytes are responsible for nuisance toxic algal blooms. In the littoral zone, submerged, floating-leaf, and emergent plants draw CO₂ (or HCO₃⁻) from the water or CO₂ from the atmosphere. Most of these are higher (vascular) plants, but multicellular charophyte algae and aquatic mosses (bryophytes) are also common, as are epiphytic diatoms living on the surface of the substrate or on plants. Some taxa of charophytes that live in hard water deposit a carbonate mineral coating on their surfaces.

After these plants die, their remains sink toward the lake bottom. A large percentage of particulate organic matter is grazed by zooplankton or respired under oxic conditions. Respiration releases CO₂ back into the lake water, and hypolimnetic CO₂ saturation can be orders of magnitude above atmospheric equilibrium. The remaining organic matter, along with precipitated carbonate minerals and detritus washed into the lake, accumulates on the lake floor. Diagenetic (postdepositional) alteration of this material can occur under oxic or anoxic conditions. Which conditions prevail at the sediment-water interface and in the lowest part of the water column depends upon the flux of organic matter (and other reduced materials) relative to the concentration of oxygen in the bottom waters and its rate of resupply. Lake sediments are almost always anoxic due to the relatively high organic carbon content (a few percent to over 40%) and the slow diffusion rate of oxygen through overlying and pore water. The oxic-anoxic transition, then, typically occurs around the sediment-water interface, and in some lakes with high sediment oxygen demand, higher in the water column. This hypolimnetic oxygen depletion may be seasonal (e.g., occurring only under summer stratification or under winter ice cover),

or it may be persistent or permanent if the water column remains unmixed. Under anoxic conditions, methane-producing bacteria (methanogens) in the sediment or water column reduce dissolved CO₂ or ferment organic molecules and release CH₄. Dissolved methane may diffuse through the water column, and be consumed by methanotrophic bacteria at the oxic-anoxic transition, or it may come out of solution and bubble out of the lake water to the atmosphere (e.g., Walter et al., 2006). Carbonate minerals may partially or fully dissolve while sinking in the water column, or in the sediments, because the release of CO₂ by respiration lowers pH and increases carbonate solubility (e.g., Dean, 1999).

Carbon isotopes

Photosynthesis and respiration exert the main controls on the carbon stable isotopic composition of DIC. In surface waters, photosynthesis preferentially takes up ¹²C into organic matter, leaving the DIC pool enriched in ¹³C ("heavy"). Respiration of this "light" sinking organic matter releases ¹³C-depleted DIC into the bottom waters, causing the hypolimnetic DIC pool to become lighter (Hollander and McKenzie, 1991). A typical profile of δ¹³C of DIC in a lake is shown in Figure 2. In some lake systems, microbial processing of organic matter in anoxic bottom waters exerts some influence on δ¹³C of DIC (Myrbo and Shapley 2006): in lakes with relatively high sulfate, dissimilatory sulfate reduction using an organic molecule as an electron donor generates HCO₃⁻ with a δ¹³C reflecting the relatively light organic matter source. In contrast, methanogenesis generates very ¹³C-depleted CH₄ and leaves the DIC pool ¹³C-enriched or heavy. Carbonate minerals in the catchment and dissolved carbonate in groundwater and surface water also contribute to the δ¹³C of lake water. These sources are typically isotopically heavy if the C is derived from carbonate minerals, and light if derived from oxidation of organic matter. Because of these inputs, in-lake processing, and disequilibrium with atmospheric CO₂, lake surface δ¹³C values are not readily predicted. Similarly, the radiocarbon (¹⁴C) content of surface water DIC is not typically in equilibrium with atmospheric values, and thus radiocarbon dating of aquatic organic matter (i.e., material whose carbon source was DIC rather than atmospheric CO₂) usually provides a date that is "too old" relative to the date the organism actually died.

Carbon accumulation and the sedimentary record of lakes

Particulate carbon accumulates in lake sediments as carbonate minerals (usually calcite) and a variety of organic remains representing the organisms that lived in and around the lake. These two components together can comprise nearly 100% of the sediment in some lakes, though diatoms and detrital mineral debris usually occur in significant percentages as well. Organic remains are dominated by algal and higher-plant debris, including both altered (charcoal, carbonized soil organic matter) and unaltered

Carbon Cycle in Lakes, Figure 2 Generalized profile of the carbon stable isotopic value of dissolved inorganic carbon ($\delta^{13}\text{C}_{\text{DIC}}$) in a lake over the period from holomixis through summer stratification. Photosynthesis drives values more positive, or “heavier,” while respiration drives values more negative, or “lighter.” In lakes with significant methanogenesis in the sediments, a positive shift is seen in values near the sediment surface.

tissues, with a smaller contribution from invertebrates such as insects, cladocerans, ostracodes, etc. Vertebrates are extremely rarely represented, although fish remains (teeth and sometimes scales) do occur.

Small lakes typically have higher sedimentation rates than larger lakes, due to their high shoreline-to-open-water ratio, which leads to both more direct particulate input of surficial material and usually more input of nutrients and other dissolved species, potentially supporting higher productivity and more mineral precipitation, respectively. Pelagic sedimentation rates in large,

oligotrophic lakes may be on the same order as those of the ocean, at <0.02 cm/year (in terms of linear accumulation rate) or <0.01 kg/m²/year (mass accumulation rate; these figures are examples and not necessarily related to one another). In small lakes, especially in urban and agricultural regions, rates can exceed 1 cm/year or 5 kg/m²/year (e.g., Engstrom et al., 2007). Littoral zones experience both deposition and erosion, and thus are difficult to compare with the profundal zone, but sediments tend to be dominated by minerogenic material relative to organic material, due to wave-reworking and removal of low-density organic matter, and decomposition under oxic conditions. Lakes’ relatively organic-rich sediments make them excellent (though relatively small) potential hydrocarbon source rocks (Kelts, 1988). Mesozoic rocks representing lacustrine deposition in former rift basins of coastal Brazil and West Africa, for example, have recently been exploration targets. The small size of most lakes and rapid sedimentation rates mean that most are geologically transient features, lasting perhaps 10,000–100,000 years, although large lakes in tectonically active regions (e.g., modern lakes of the East African Rift, and Eocene lakes of the Green River Formation) can persist for millions of years due to basin subsidence and the resulting increase of accommodation space.

The study of core samples of lake bottom sediments (paleolimnology or limnogeology) can provide a long-term record of environmental changes in and around a lake. Compositional, geochemical, and biological analyses are routinely used to “reconstruct” past climate changes, geological processes, and human impacts. Some records collected extend back more than one million years, and can provide approximately decadal or better resolution of changes in the lake and the surrounding region. Stable isotopes of carbonates and organic matter in the sedimentary record are used as “proxies” for past productivity, organic matter source (e.g., aquatic vs. terrestrial) and water column stratification and circulation.

Acknowledgments

This is LRC contribution number 12-01.

CARIBBEAN-CENTRAL AMERICA, LAKES REVIEW

Rhodes W. Fairbridge (Deceased)

Introduction and generalities

The Caribbean Sea is properly an arm of the Atlantic Ocean that is rimmed to the north and east by the West Indies or Caribbean islands, comprising the *Greater Antilles* (Jamaica, Cuba, Hispaniola, and Puerto Rico) and the *Lesser Antilles*, the *Windward Islands*, that is Virgin Is. to Dominica, and the *Leeward Is.*, and the southerly ones, Martinique to the Grenadines and Grenada. Also included in the Leeward Is. are the so-called ABC ones (Aruba, Bonaire, Curaçao). In addition, but separate, are Barbados, Trinidad, and Tobago. Likewise separate and distinctive are the Bahamas, and Turks and Caicos Is.

Central America is taken to embrace the continental area from the Mexican border to northwest Colombia, that is, Guatemala, Belize, Honduras, El Salvador, Nicaragua, Costa Rica, and Panama, a total area of 592,017 km² (228,578 square miles). Its highest point is the Tajumulco volcano in Guatemala (4,220 m, 13,845 ft). The region lies entirely in the northern hemisphere, from north of the Tropic of Cancer, about 27°N, to about 7°N, and from 59°W to 92°30'W.

Geologically, the mainland belt represents an elongated isthmus that has fluctuated in height and width since Mesozoic times, but has been severed repeatedly, permitting an intermittent marine link (Tethys) to bring “mediterranean” biota to the western Pacific. Because of tidal

cycles, the marine currents in Tethys were generally east to west. The last interruption was in Pliocene times when land faunas began their exchanges between North and South America and marine endemism began in the eastern Pacific. The principal rock formations are therefore mainly volcanic, of various ages. Exceptionally, in Guatemala, there are fossiliferous marine Permian formations.

During plate tectonic history, the North American and South American plates have jostled repeatedly, as they fractured away from the Eurasian and Gondwana landmasses, the taphrogenesis beginning in late Triassic to early Jurassic times. The main fault systems were strike slips, those in the north being mainly sinistral (SW–NE, E–W, and NW–SE), while those in the south are mainly dextral (NE–SW and E–W).

In the Greater Antilles, the geological record goes back to the Paleozoic, but is nevertheless marked by an alternation of relatively deep-sea marine formations and volcanic intervals. Because of the tropical climates, limestones are particularly prevalent, and today some of the world’s more spectacular karst landscapes are to be found in Cuba and the other islands.

Drowned karst (with its “Blue Holes”) is a feature of the Bahamas.

The Lesser Antilles, in contrast, have long been dominated by a west-dipping subduction zone which results in the twin arcs of islands, a style first recognized in the East Indies (Indonesia). The outer arc (the Atlantic site) is marked by nonvolcanic, mainly limestone islands (Virgin Is., Antigua, and Barbados), while the inner arc (the Caribbean side) is marked by much more numerous volcanoes (St. Kitts, Montserrat, Guadalupe, Dominica, Martinique, St. Lucia, St. Vincent, Grenada, etc.). Related to the outer arc are the limestone banks of the Bahamas, and Turks and Caicos Is., that are ancestrally related to Florida and their ancient Gondwana foundation.

Climatically, the entire area is dominated by the northeast trade-wind system, but is subject to a great deal of orographic modification. Furthermore, there is the diurnal sea-breeze/land-breeze effect. There is little seasonality and practically no continentality. Orographic rains are thus normal in almost every month but heavier in the northern summer. Because of the rain shadow effect, certain areas are semiarid (e.g., northwest Costa Rica; much of Haiti). Tropical cyclones and hurricanes are commonly experienced in the islands but less so on the mainland shores. These occur as a rule in May–June and September–October, starting off the coast of West Africa, gaining strength in the warmer sea-surface temperatures of the Western Atlantic, building over the Caribbean to full-fledged hurricanes, bearing to the right, and impinging on Puerto Rico or Cuba before heading north.

Lake classification

Categories of lakes in this region are few in number compared to the larger continental unities, partly because of their low latitudes and partly because of lack of any

Caribbean-Central America, Lakes Review, Figure 1 Distribution of lakes in Caribbean-Central America. 1, Chapala; 2, Patzcuaro; 3, Texcoco; 4, Catemaco; 5, Cuitzeo; 6, Atitlan; 7, Terminos; 8, Izabal; 9, Cartasco; 10, Managua; 11, Colciboica; 12, Nicaragua; 13, Humedal C. endorheic drainage. The important lakes are shown in (Figure 1).

Structural

Structural depressions of complex graben type are present both in the mainland and in the Greater Antilles (Cuba and Hispaniola).

1. *Lake Nicaragua* (4,960 km², 3,100 square miles) is 163 km (102 miles) long and 70 m (230 ft) deep. It is the largest lake in Central America. It is linked to Lake Managua by the Tipitapa R in the north and drained in the southeast by the San Juan R. that debouches into the Caribbean.
2. *Lake Managua* (220 km², 575 square miles) is 61 km (38 miles) long. The capital city of Nicaragua, Managua is situated on the southwest side.
3. *Lago de Izabal*, situated in eastern Guatemala, draining northeast via the Dulce R to the Caribbean, it is controlled by a NE-SW trending graben.
4. *Etang Saumatre*, a swampy salt lake in the southeast part of Haiti, it is about 30 km east of Port-au-Prince.
5. *Lago Enriquillo*, a salt lake, similar to E. Saumatre (Haiti), 45 m (150 ft) below sea level, it is in the southwest part of the Dominican Republic.

6. *Lago Gatun*, situated about 10 km south of Colon, the Atlantic end of the Panama Canal, the Gatun Lake is now connected with the canal and its locks.

7. *Lago Bayano*, 35 km long and situated south of the Cordillera San Blas in eastern Panama, the lake drains into the Gulf of Panama.

Volcanic

Crater lakes are numerous, although generally small. When the volcano is dormant, the lake is generally a picturesque tourist attraction, and sediment coring may provide a useful historical record. However, when the igneous activity is revived, the lake sediments become converted into a boiling mud that is likely to generate a lahar that may have catastrophic impact on the populations of the lower slopes. The waters of crater lakes range from highly acidic (e.g., pH 2.7, L. Alegria) to alkaline (pH 9.9, L. Nejapa).

1. *Lake Arenal*. Located in Costa Rica, the volcano, 1,960 m (6,429 ft) high, erupted last in 1968, but the rift (15 km to northwest) is occupied by a spectacular lake.
2. *L. Irazu*. Also in Costa Rica, near the city of Cartago, the Irazu volcano erupted in 1841, 1910, and 1963. It is said that on a clear day, it is the only place where both

Atlantic and Pacific oceans can be seen at the same time. During the last activity, water-saturated tephra (ash) created a major lahar.

3. *Lago Poás*. Likewise in Costa Rica, 30 km northwest of the city of San José. The volcano is 2,708 m (8,884 ft) high. Pictures of its February 1953 steam eruption in the lake were shown in the Fairbridge (1968) *Encyclopedia of Geomorphology* (p. 220).
4. *Lago Nejapa*. Associated with a line of volcanoes in western Nicaragua, extending northwest from the Lago de Managua, this lake is distinguished for its extreme alkalinity (pH 9).
5. *Laguna de Alegria* on the Tecapo volcano of El Salvador, with four other lakes in this small country. It is notable for the extreme acidity (pH 2.7) of its waters.
6. *Lago de Atitlan*. Situated in a major caldera depression at an elevation of 1,433 m (4,700 ft) in western Guatemala, this lake is about 20 km (12 mi) wide and 300 m (1,000 ft) deep. A youthful volcanic cone 354 m (11,604 ft) high rises south of the lake.

Karst lakes

Extensive areas of limestone terrain associated with karst features are found in Cuba, Hispaniola, and Puerto Rico and in the north part of Guatemala (a karst landscape that extends into southwest Mexico and Yucatan). Sinkholes are commonly associated with small lakes and then known as "cenotes." The latter played an important religious role with the ancient Mayan people.

The karst lakes involved are small and do not constitute major features.

Coastal lagoons

These are scarce on the Pacific coast of Central America, but common on the Atlantic Coast, facing the Caribbean. Here, the coasts are subject to the northeast Trade Winds and periodic hurricanes. From north to south, the principal features are:

1. *Belize coast*. It is largely protected by offshore coral reefs (barrier reefs).
2. *Honduras coast*. A north-facing shore with a number of west-growing sandspits but without forming closed lagoons. The largest example is the *Laguna Caratasca*.
3. *Nicaragua coast*. The "Mosquito Coast" is well-named because it is oriented N-S and is low and swampy, but few lagoons are closed. The largest is the *Laguna de Perlas*.
4. *Costa Rica's Caribbean coast* is similar, and the northwest part is identified as the "Parque Nacional Tortuguero." The southeast contains the site of the "Parque Internacional La Amistad."
5. *Panama Coast*. In the west is the island-studded *Laguna de Chiriquí*. East of Colon are several national parks, but the numerous islets (Archipelago de San Blas) do not form closures.
6. *Cuba Coasts* are marked by numerous archipelagos parallel to the shores, but without closed lagoons, except on the offshore island *Isla de la Juventud* which has several small lakes.
7. *Hispaniola Coasts* lack lagoons except for one northeast of Cabo Beata in southwest Dominican Republic.
8. *Puerto Rico Coasts* lack closed lagoons except for a few small examples on the south coast (e.g., L. Guánica).
9. *Coasts of Jamaica*. Jamaica's north coast is rocky or fringed by coral reefs. However, the south coast is low and swampy with many small lagoons, e.g., Black R. to Parotee Point, Alligator Pond, the Alley to Rocky Pt, Hellshire Hills, and The Salt Ponds (near White Horses) speak for themselves.
10. *Coasts in the Bahamas, and in Turks and Caicos Is.* These islands are, for the most part, associated with bank margins, that is, with deep water on one side and shallow on the other. In consequence, they are, except for *Andros*, mostly long and narrow. A second exception, in the far south, is *Great Inagua* which contains a major enclosure, *Lake Rosa*, 30 km long, and a small one at Matthew Town.
11. *Coasts in the Lesser Antilles*. Most of the islands are volcanic but lacking in lakes, while the remainder are small, limestone features. The latter include the Netherlands Antilles, the "ABC islands" of *Aruba*, *Bonaire*, and *Curaçao*, of which Bonaire includes a lagoon, famous among geologists for its precipitation of dolomite.
12. *Trinidad and Tobago Coasts*. These islands represent geological extensions of the Northern Cordillera of Venezuela, separated from them by the Gulf of Para. Sandspits along the east coasts, e.g., Cocos Bay, do not contain lagoons. On the west side is the Caroli Swamp.

Asphalt lake

On Trinidad a unique product of mud-volcano activity, driven by tectonics and hot waters with petroleum products, is a large tar seepage that has long been known as the Asphalt or Pitch Lake. The asphalt was exploited for many years for sealing boats and for waterproofing the roofs of dwellings. The natural upwelling of the hot water and tar has always replaced the quantities removed from the surface.

Dams and reservoirs

Central America is not featured by any world-class dams and reservoirs, but is distinct for one particular system, the Lago Gatun and the Lago Alajuela which are modified to provide the daily demands for refilling the locks of the Panama Canal.

Climatically favored by the northeast trade winds, most of the continental areas of Central America and both the Greater and Lesser Antilles are well watered, but certain areas are marked by rain shadows and as a result are

semiarid. In those places, the natural vegetation reverts to a cactus scrub, although there are no actual deserts. Normally, the trade-wind clouds are intercepted by the elevations and furnish almost daily precipitation. Some parts of southern Cuba, much of Haiti, and parts of the Dominican Republic are affected by droughts or are generally semiarid.

In Honduras, the *Represa el Cajon* (reservoir) is situated 40 km southeast of San Pedro Sula. There are several in El Salvador and Nicaragua. Numerous small reservoirs occur in Cuba and Puerto Rico.

CARINTHIA LAKES AND RESERVOIRS IN AUSTRIA

Hans Sampl

Kärntner Institut für Seenforschung, Klagenfurt, Austria

Introduction

Carinthia is a southern province of Austria and situated at the border to Italy and Slovenia. There is hardly any alpine region containing so different types of lakes, littoral zones, and various types of landscapes within a similar limited space. Their specific character depends to a minor extend on their surface area but is based predominantly on a till 28°C warm epilimnion and the meromictic mixing of

some of the lakes. There are around 1,270 stagnant water bodies in Carinthia, including some high alpine pools and artificial ponds.

630 of that stagnant water bodies are situated in an altitude above 1,000 m, most of them being rather small with surface areas of less than 0.1 ha. The cumulated surface of all stagnant water bodies in Carinthia covers 60 km², to which the four largest Wörthersee ([Photo 1](#)), Millstätter See, Ossiacher See, and Weissensee ([Photo 2](#)) contribute 50 km² ([Figure 1](#)). In [Table 1](#), all lakes larger than 19 ha are listed. The deepest lake is Millstätter See with 141 m, followed by Weissensee (99 m) and Wörthersee (85 m).

The Carinthian lakes are geological rather young and were formed at the end of the last ice age, when the large glaciers withdrew around 15,000–12,000 years BC. The general shape of the basins was in many cases determined by the tectonic shape of former old valleys. The formation of lakes is based on glacial erosion of the valley floors and the deposition of moraines.

The chemical composition of the water is shown in [Table 2](#).

The manifold landscapes around the lakes have inspired nature lovers and artists like Johannes Brahms, Gustav Mahler, and Alban Berg long before the establishment of modern tourism. The settlement of monasteries and convents like St. Georgen am Längsee (founded about 1002–1018), Millstatt (founded between 1060 and 1091), and Ossiach (founded about 1028) could have been influenced by the fact that the lakes with their rich stocks of fish provided an excellent Lenten fare. During the last years, professional fishing ceased, and nowadays, fishing is performed nearly exclusively by sport fishers. Angling

is a prominent part of touristic attractions. Relicts of lake dwellings in Keutschacher See testify an early settlement since Bronze Age ("Hallstattzeit").

The touristic attractions at the lakes contain any kind of water sports. Generally motorboats on lakes are prohibited: exceptions exist for regular shipping routes on the four large lakes, as well as for professional use including fishing, Taxis, fire fighters, etc. A limited number of licenses for private boats are distributed at

Wörthersee and Ossiacher See, but additional boats are not allowed. Sailing is permitted on all of the large lakes.

All the lakes are situated beyond the main discharge lines and are not fed by the river Drau and its dominant tributaries. The catchment areas of the lakes are small, and as a consequence, they have a low rate of water exchange. For example, Wörthersee needs theoretical 10.5 years for a complete renewal of the water body, Klopeiner See 11.5 years, respectively.

Carinthia Lakes and Reservoirs in Austria, Figure 2 Development of temperature stratification [°C] in four Carinthian lakes (Kärntner Institut für Seenforschung).

Peculiar limnological features

Temperature regime

The low rate of water exchange, the weak winds in valleys and basins, where lakes are situated, and an intensive solar radiation during the summer are causes for high surface temperatures up to 25°C in the epilimnion and even up to 28°C in littoral zones. Characteristic is a strict temperature-induced stratification with a reduction of temperature to 4°C in the metalimnion within a few meters (Figure 2). The high surface temperatures during the period of May till September – when most lakes in low altitudes are well suited for swimming and various water sports – are reason for the development of an intensive summer tourism.

When bad weather approaches during autumn, the water cools down rapidly, and the smaller the surface of a lake, the earlier it freezes. In small lakes, the ice cover sets in during November or December, whereas large lakes freeze normally in January. No ice coverage occurred on the large lakes Wörthersee, Millstätter See, and Ossiacher See during mild winters. In contrast, the small lakes freeze every year. The thickness of the ice changes considerably from year to year and attains, in most cases, 20–30 cm. The ice offers a lot of opportunities for winter sports, especially skating. The period of ice coverage varies in lakes situated in valleys and basins between 3 weeks up to 3 months, depending on weather conditions and altitude. Lake Weissensee is situated at an altitude of 930 m and is covered for 4 months, whereas the ice persists for 6 months on Turracher See at an altitude of 1,763 m.

Meromixis

A peculiarity of Carinthian lakes is their meromictic type of mixing. Tables 1 and 3 contain a list of the meromictic lakes Wörthersee, Millstätter See, Weissensee, Klopeiner See, and Längsee. The shelter from winds and the low flow rate are reasons of meromixis. The phenomenon of meromixis was described first by Findenegg (1933). The

discovery of meromixis has been described by Findenegg in the following way (translation of the original text in German):

“During the winter 1931/32 I investigated the variation within the stratification of carinthian lakes somewhat comprehensively. The result can be summarized that the majority of these lakes do not exhibit the expected full circulation at the beginning and end of the winter stratification, but that the deep water body remains all year long in permanent stagnation, thereby causing exceptional high O₂ depletion in the lower hypolimnion. Although those lakes belong without doubt from the aspect of production to the group of oligotrophic lakes, one detects in the depth such small quantities of O₂, that even extremely eutrophic waters with regular circulation patterns are fairly exceeded.

This is combined with a relevant formation of sapropel in deep regions and sometimes even with a not insignificant H₂S content. It is appropriate to use the expression pseudo-eutrophic for these conditions within the deep parts of the hypolimnion.

Of course it is not intended, to predetermine with this term the productivity of the lake; rather according to the trophic status, those lakes belong to the oligotrophic type and it is the intention to categorize by hydrographic means a lake in which the conditions occur due to the permanent stagnation of deep strata, as this is typical for highly eutrophic lakes during the late summer.

The appearance of pseudo-eutrophic oxygen stratification can be seen in all carinthian lakes that are either rather small but not as shallow as the Klopeiner See, or in larger lakes with considerable depth whose basins are rather elongated and narrow, as is the case in most inner alpine lakes.”

For the meromictic cycling of Carinthian lakes, the factors low flow-through-rate, position in wind sheltered basins, and a certain relation between depth and surface area are important. The actual range of mixing depends

Carinthia Lakes and Reservoirs in Austria, Table 3 Characteristics of meromictic Carinthian Lakes

Name of lake/Dimension	Area (ha)	Max. depth (m)	Mean depth (m)	Extension of mixolimnion	
				av. (m)	max. (m)
Wörthersee	1,938.8	85.2	41.9	40.0	70.0
Millstätter See	1,328.1	141	88.6	60.0	100.0

Längsee	74.8	21.4	13.4	9.0	21.0

Carinthia Lakes and Reservoirs in Austria, Figure 3 Stratification of temperature [°C] and oxygen [mg/l] in the meromictic Lake Wörthersee during the spring mixing period (11.03.1981) (Kärntner Institut für Seenforschung).

on the weather conditions that are changing from year to year (Findenegg, 1933, 1937; Frey, 1955; Harmsworth, 1984). A typical stratification of temperature and oxygen during mixing period is shown in Figure 3.

During the past years, occasionally full mixing occurred in several lakes. The reason may be seen in a short period of ice cover due to climatic changes.

Plankton and benthos

Though the plankton in various types of lakes is considerably heterogeneous, a certain general character can be recognized. In oligotrophic lakes like Weissensee, Faaker See, and Klopeiner See, the dominant algal groups consist of Bacillariophyceae, Dinophyceae, and Cryptophyceae. In weakly mesotrophic (oligo-mesotrophic) lakes, the dominant algal groups are pennate Diatomeae, Cyanophyceae, Chlorophyceae, and Cryptophyceae.

A peculiarity of strictly stratified meromictic lakes is the occurrence of *Planktothrix rubescens*. No other organism of Carinthian lakes caught so much interest in scientists as well as in the public community. Popularly, it is called “red algae.” It was observed for the first time in 1906 at Wörthersee; in relevant quantities it appeared during the 1930s and colonized primarily Wörthersee, Keutschacher See, and Längsee. In 1959 and 1960, it was recorded for Ossiacher See, in 1961 for Millstätter See, and in 1962 in Wörthersee in larger quantities and

even in form of algal blooms. The organism exhibited a significant behavior. During late autumn and winter, when the cycling of water masses had already initiated, the species is distributed uniformly within the whole water body. One can recognize that phenomenon with bare eyes because at that time the lakes contain a considerable turbidity and a rusty brown or brownish color.

After freezing these primarily, singular filaments clump together and can be recognized below the ice as red flakes. In spring, after the melting of the ice, *Planktothrix* becomes again distributed uniformly throughout the entire water body after the mixing process. With the warming of the surface water and the increasing radiation, the species starts to withdraw from the surface and retires into the metalimnion. As a consequence, the epilimnion is nearly devoid of *Planktothrix* filaments since May or June. During the whole summer, this algal species spends in the metalimnion and concentrates between 10 and 12 m to maximal densities of 92 g/m³, where it attains a good development in spite of the unfavorable light conditions. *Planktothrix* deprives the epilimnion from a considerable amount of nutrients, and therefore, the epilimnion remains poor in nutrients, contains a low biomass of phytoplankton, and reveals a high transparency (Kärntner Seenerichte 1975 till now, every year).

Planktothrix showed this behavior for many years. When the nutrient levels of the lakes increased during

the 1960s because of increasing wastewater discharge, this kind of behavior switched totally. Their biomass increased and the zones of maximal density were dislocated from the metalimnion to the surface. This could be observed for the first time in Wörthersee in 1963. At the peak of eutrophication – in the years 1968 till 1972 – the species came to the very surface in the summer. The entire surface of Millstätter See was covered with a thick layer of reddish-brown flakes and aggregates. The same phenomenon occurred in other lakes as well, creating disgusting aggregations. Since the construction and finishing of sewer systems lead to a marked decrease of nutrient levels, *Planktothrix* switched again to its normal behavior – stratifying in the metalimnion. The entire surface of Ossiacher See was covered by algal blooms of *Anabaena flos-aquae* and *Microcystis aeruginosa* during the period of enhanced eutrophication from 1971 to 1972. Since the construction of sewer systems, these phenomena did not occur any more.

The zooplankton consists of following genera/species:

1. Rotatoria: *Polyarthra*, *Keratella*, *Kellicottia*, *Filinia*, *Trichocerca*, *Pedalion*, *Pompholyx*, *Ascomorpha*, *Synchaeta*, *Gastropus*, *Asplanchna*
2. Cladocera: *Daphnia hyalina*, *D. longispina*, *D. cucullata*, *D. galeata*, *Bosmina coregoni*, *B. longirostris*, *Diaphanosoma brachyurum*, *Ceriodaphnia quadrangula*, *Leptodora kindtii*, *Bythotrephes longimanus* (only in Millstätter See)
3. Copepoda: *Eudiaptomus gracilis*, *Eudiaptomus graciloides*, *Cyclops abyssorum*, *Mesocyclops leuckarti*, *Thermocyclops hyalinus*, *Mixodiaptomus laciniatus*, *Arctodiaptomus alpinus* (only in mountain lakes)

It has to be mentioned that larvae of *Chaoborus* sp. (midge, Diptera) occur in lakes with anoxic or low-oxygen-saturated water in the hypolimnion. A biological peculiarity is the presence of the limnic jellyfish *Craspedacusta sowerbyi*, which is occasionally frequent in warm summers.

The benthic community is characterized by the occurrence of the mussel species *Anodonta cygnea*, *A. anatina*, *Unio pictorum*, and *Dreissena polymorpha*, the latter occurring in Carinthian lakes since 1972, when it was introduced by tourist boats.

Large areas of the benthal are devoid of faunal organisms due to the lack of oxygen in the profundal of meromictic lakes. In the littoral zones, the ubiquitous species of dragonflies (Odonata), chironomid midges, Oligochaeta (*Tubifex*), water snails (*Viviparus*, *Planorbis*, *Limnaea*) are present.

With the invasion of the crayfish pest – an infection of the ascomycetic fungus *Aphanomyces astaci* – the former frequently distributed freshwater crayfish species (*Astacus astacus*, *Austropotamobius pallipes*, *A. torrentium*) were extincted or strongly decreased respectively. The indigenous crayfish *Astacus astacus* has relict areas in some lakes. The former dense populations were extincted with

the introduction of the North American species *Orconectes limnosus* and *Pacifastacus leniusculus*.

The fish fauna consists of following species:

Lake trout (*Salmo trutta* f. *lacustris*), charr (*Salvelinus alpinus*, Millstätter See, mountain lakes), whitefish (*Coregonus lavaretus*), pike (*Esox lucius*), carp (*Cyprinus carpio*), bream (*Abramis brama*), white bream (*Abramis bjoerkna*), bleak (*Alburnus alburnus*), shemaya (*Chalcalburnus chalcoides mento*, only in Wörthersee), crucian carp (*Carassius carassius*), chub (*Leuciscus cephalus*), minnow (*Phoxinus phoxinus*), bitterling (*Rhodeus sericeus*), roach (*Rutilus rutilus*), rudd (*Scardinius erythrophthalmus*), green tench (*Tinca tinca*), vimba (*Vimba vimba*), wels (*Silurus glanis*), burbot (*Lota lota*), perch (*Perca fluviatilis*), pike-perch (*Stizostedion lucioperca*), loach (*Barbatula barbatula*).

Introduced species: pope (*Gymnocephalus cernuus*), pumpkin-seed (*Lepomis gibbosus*), largemouth bass (*Micropterus salmoides*), (*Pseudorasbora parva*), grass carp (*Ctenopharyngodon idella*), silver carp (*Hypophthalmichthys molitrix*), eel (*Anguilla anguilla*).

As a peculiar feature is the indigenous *Coregonus lavaretus* of lake Wörthersee, which has been stocked in other regional lakes too. Charrs (*Salvelinus alpinus*) are the typical fish of alpine lakes, which attain a length of up to 15 cm in a special dwarfed form (“Schwarzreuther”) due to scarcity of food. Professional fishing is rare in Carinthian lakes, most fishing is exerted as angling, where especially lake trout (*Salmo trutta* forma *lacustris*), pike (*Esox lucius*), wels (*Silurus glanis*), and pikeperch (*Stizostedion lucioperca*) belong to the most attractive prey. Further, there is the largemouth bass (*Micropterus salmoides*) which has been introduced in 1900 and could establish stable populations only in Wörthersee and Keutschacher See among all central European lakes.

In contrast to the dense settlement along the shores of all large lakes, there remained still zones with natural vegetation, consisting of reed (*Phragmites australis*), rush (*Scirpus lacustris*), water lily (*Nymphaea alba*), yellow water lily (*Nuphar lutea*), pondweed (*Potamogeton* sp.), water milfoil (*Myriophyllum* sp.), soft hornwort (*Ceratophyllum submersum*), muskgrass (*Chara* sp.).

Eutrophication

The initiation of an intensive summer tourism in the early 1950s and the crescent prosperity of the population at the lakesides and the catchment areas induced a considerable wave of eutrophication. Overnight lodging within the catchment area of Wörthersee increased within three decades from 500,000 up to three million in the year 1980. The wastewaters were either poorly treated or directly discharged into the lakes or their tributaries. Consequences were hygienic inconveniences with enhanced numbers of fecal bacteria in littoral regions and considerable loads of phosphorous and nitrogen compounds. The concentrations of total phosphorous increased steadily.

The concentrations of phosphorous – being the limiting element for algal growth in Carinthian lakes – increased continuously. For example, the annual load of phosphorous discharged into Wörthersee was 20–22 and 23 t for Millstätter See. This continuous input of nutrients intensified the growth of phytoplankton in the epi- and metalimnion. Water transparency decreased with the growth of algal biomass, and the decomposition of algal biomass in the profundal zones consumed oxygen and decreased its content in the hypolimnion (Figure 4). The accelerated growth of phytoplankton and a spectacular lead in 1963 for the first time at the western bay of Wörthersee to mass aggregations of *Planktothrix rubescens* algal bloom. The continuous process of eutrophication culminated in many lakes in the period of 1968–1973. From 1970 to 1973, an algal bloom of *Planktothrix rubescens* covered the entire surface of Millstätter See. In Ossiacher See, the bloom consisted of *Microcystis aeruginosa* and *Anabaena flos-aquae* and covered the entire surface too. Other lakes had mass developments of macrophytes (Afritzer See, *Elodea*

canadensis), and in some lakes, the proceeding of eutrophication was visible in the growing deficit of oxygen in the hypolimnion.

Sanitation

The pressure of deficits in water quality since 1963 – hygienic problems in the littoral, large-scaled algal blooms covering entire lakes – evoked projects for the prevention of wastewater discharge by construction of sewer systems. All wastewaters of domestic origin within the hydrographic catchment area were collected in sewer systems and drained to wastewater treatment plants. Those plants were situated at the lakes runoff or at other rivers, preventing a further loading of lakes with their nutrients. This was possible in the Carinthian lake district, as the catchment areas of lakes are fairly small. With this concept, even a residual loading from cleared wastewaters was eliminated. The sewer systems were constructed according to a principle, that collectors are situated either on land or in form of pumping lines within the lake, where the wastewater is transferred from pumping station to pumping station. The tubes used in the lakes are plastic pipes that were extruded at the lake in the form of endless tubes and then sunk to the ground.

For the management of the sewerage projects, so-called sewage associations were established that organized engineering, planning, construction, and financing as well as the maintenance of the sewer systems. The peculiarity of this kind of lake sanitation was the complete avoidance of residual loading by wastewater and, according to technical and topographical opportunities, the installation of pumping lines at the bottom of a lake. The fundamental principle was the establishment of sewer systems in the entire catchment area of the various lakes.

With the collection of wastewaters in sewers, the hygienic situation at littoral sites improved immediately, and all limits and guide values of the “Directive on the quality of bathing water 76/160/EEC” as well as the Austrian law “Badegewässerverordnung, BGBl. (BGBl. II 429/2009)” are fulfilled at any time, and the values fall by far below the limits. There are no objections with

respect to the hygienic conditions (EU-Report: “Quality of bathing water,” yearly). With the limitation of anthropogenic nutrient inputs, the concentration levels of phosphorous and algal biomass improved continuously. Algal blooms of cyanobacteria (blue-green algae, Cyanophyceae) did not occur since then, and the water transparency increased since the summit of eutrophication (between 1969 and 1972, Figure 4) significantly yet in individual patterns. The re-oligotrophication process is described by Sampl (1982), Sampl et al. (1982), and Kärntner Seenbericht (1975) till now (every year).

As additional actions of lake sanitation (restoration, therapies, internal actions), the following were executed: removal of sediments with high nutrient contents (Ossiacher See, Pressegger See), aeration of the hypolimnion (Feldsee), draining-off of hypolimnic water (Klopeiner See), and removing an excess of macrophytes.

The province of Carinthia achieved in 1991 the “Tourism for tomorrow award” (European winner 1990 for clean lakes in Carinthia) for its successful restoration of Lakes.

Storage reservoirs

Storage reservoirs have been constructed in the high alpine regions for the generation of hydroelectric power in storage power stations and exhibit ecological characters similar to natural lakes. The important differences are focused on the runoff which is situated at the bottom and huge amplitudes of water levels. Reservoirs attain considerable size and depth (Figure 1, Table 4) and contain a composition of phyto- and zooplankton species which is not significantly different to that in natural lakes. The main genera of phytoplankton are Bacillariophyceae (*Synedra* sp.) and Dinophyceae (*Gymnodinium* sp.), Chlorophyceae, Cryptophyceae, and Cyanophyceae (*Phormidium* sp.). The species of zooplankton are the same like those in the lakes, additional *Arctodiaptomus alpinus*. Some reservoirs were constructed by damming up natural alpine lakes and thereby changed to reservoirs of increased size and depth (Oschentsee, Zirmsee, Großsee, Major and Minor Mühldorfer See). In accordance to the high altitudes, the period of ice coverage lasts 6–8 months and the thickness of the ice can surpass 1 m.

Benthic organisms do not occur in areas that fall dry in periods of low water level. In the residual reservoir larvae of chironomids, oligochaeta, and mussels (Fam. Sphaeriidae) are present.

Fish exhibit a poor species diversity and originate from specimens that were stocked. A self-maintaining population of charrs (*Salvelinus alpinus*) developed in some of those reservoirs; nevertheless, the population contains dwarfed individuals called “Schwarzreuther” to a high degree. Additional brown trout, rainbow trout, lake trout, and minnows have been stocked.

River dams

A series of dams were constructed at the main river Drau (Figure 1; Table 5). The reservoirs cannot be classified as lakes in the classical sense but are river courses with extremely decreased streaming velocity. Nevertheless, they cover a considerable area. The former mere technological construction of shores has been restored according to principles of biological engineering in the past years by the formation of islands and shoals.

The former bad quality of water (α -mesosaprobic) became better since cleaning the domestic and industrial wastewater. Now, the river Drau is in β -mesosaprobic condition.

The faunal composition of fish is poor in species, with bream (*Abramis brama*) being the dominant species. Other species are pike, catfish, chub, roach, rudd, green tench, burbot, perch, barbel, and nase (*Chondrostoma nasus*). Introduced: rainbow trout, pike-perch, carp, chrupe (*Aspius aspius*), and sterlet (*Acipenser ruthenus*).

The benthic community is characterized by the occurrence of Oligochaeta (*Tubifex*, *Limnodrilus*) and Chironomidae. Other groups are rare like Hirudinea, mussels (Sphaeriidae, *Dreissena*), snails (Lymnaeidae), and Trichoptera.

CASPIAN SEA

Mikhail V. Bolgov
Russian Academy of Sciences, Water Problems Institute,
Moscow, Russia

Physical-geographical characteristic

The Caspian Sea is the largest closed water body in the world. Five states are situated on its banks: Russia, Azerbaijan, Islamic republic Iran, Kazakhstan, and Turkmenistan. The area of the sea at present equals to 0.4 million km² making 18% of the total area of lakes of the Earth. The volume of water equals to 79,000 km³. The maximal extension of the sea from north to south equals to 1,200 km, its width varies from 200 up to 450 km, and the greatest depth equals to 1,025 m.

The Caspian Sea accepts water of 130 rivers from the catchment area which is approximately ten times greater than its own one (3.5 million km²). The main feature of the hydrological regime of the Caspian Sea is significant fluctuation of its level which is the reason of significant damages and ecological accidents. The sea water level is determined by the ratio of water balance components of the water body and by possible changes of the volume of its depression ([Figure 1](#)).

According to its physical-geographical and morphological features, the Caspian Sea is subdivided into three parts: Northern, Middle, and Southern ones, and represents a huge continental depression.

The islands on the Caspian Sea occupy approximately 2,050 km². Most of the islands are located in North Caspian (more 1,800 km²). The largest among them is Chechen (122 km²), like the Tuleniy Island (68 km²), it was formed due to abruption of shallow areas during the decreasing of sea level in North Caspian.

In the eastern part of North Caspian, the Tuleniy Islands archipelago is located. Among them, Kullaly Island

(73 km²), Morskoy Island (65 km²), and many small islands can be distinguished. The majority of the sea islands of North Caspian represent accumulative formations of the bar type formed by waves on peripheral sites of raisings or structures of a sea bottom.

The Northern part of the sea is the shallowest. Its average depth is of 4.4 m. Morphologically, the border of North Caspian takes a shape of a threshold having the depths of 10–15 m. Rivers Volga and Ural flowing into North Caspian form extensive deltas overgrown by dense reed. Relic forms of river coasts, beds, and deltas are distinctive features of the morphological structure of the Caspian Sea coastal zone. The numerous relic river beds are particularly apparent in the relief of the North Caspian bottom.

Middle Caspian occupies the area of 140,000 km²; its average depth is 192 m. In this part, the sea has the least width – about 200 km. The border between Middle and South Caspian approximately coincides with 40th parallel.

The western coasts of Middle Caspian are mostly accumulative, and only several parts of the coast of Dagestan and Apsheron are abrasion ones. On the western coast, large deltas of the rivers Terek, Sulak, and Samur are located. The eastern coast of Middle Caspian is considerably lower than the western one, and there is no receipt of river sediments here. Capes and spits project from the eastern coast of Middle Caspian far into the sea, gulfs pressing into the coast between them. The biggest gulf of the Caspian Sea is Kara-Bogaz-Gol. Eastern coasts are mostly abrasion developed in limestone that composes the adjoining deserted and semideserted plateaus. In the central part of Middle Caspian (closer to the western coast), the deep Derbent depression is located with the maximal depth of about 790 m.

South Caspian has an area of 148.5 thousand km² and occupies a depression that geologically is concerned to the Alpine folding area with complex relief and the greatest depths (maximal depth is 1,025 m, the average depth is 344 m). The relief of the bottom and the shelf zone of South Caspian are characterized by numerous mud volcanoes and tectonic raisings.

The southern coast of the sea is bordered with high mountain ridge Elburus. Numerous rivers flow down into the sea from the mountains of the Iranian coast. The eastern coast of South Caspian is low up to Cheleken Peninsula in the north; deserts prevail at the seashore. To the north, the two gulfs Krasnovodsk and Turkmenian, ones divided by Cheleken Peninsula, are located.

Basic climatic features

The Caspian Sea is located within the limits of various climatic zones and is influenced by different baric centers and systems of atmospheric circulation. Local climatic features are significantly influenced by complex orography of the western and southern coasts of the sea. The greater part of the Caspian Sea is located in the moderate climatic zone. North Caspian and its coasts are located in

Caspian Sea, Figure 1 The Caspian Sea map.

a strip of continental temperate climate. The winter here is frosty, with poor snow; the summer is hot and dry. At the eastern coast of Middle Caspian, the climate is severe, of the deserted type, with insignificant amount of precipitation.

On the water area of the Caspian Sea, the atmospheric precipitation is distributed nonuniformly. Average precipitation varies from 75 mm up to 150 mm/year along the eastern coast; along the western coast, it varies from 200 mm up to 400 mm/year in the north and up to 1,200 mm/year in the south. Approximately 70% of annual norm of precipitation falls in autumn, and in winter, only 7–10% of precipitation account for the summer months. From the point of view of climate, Lencoran subtropical area is essentially different. Here, winter is soft and moist, with high air temperature, even minimal values of it fall below zero extremely seldom. Even softer is the

subtropical climate of the Iranian coast having very high humidity almost during all the year.

Wind direction and speed above the Caspian Sea are determined by general atmospheric circulation, pressure fields, and orography. Winds most often observed on the Caspian Sea are those of northwest and southeast directions with the speed of 5–9 m/s. Annual wind speed reaches the greatest values in the area of Apsheron peninsula – 6.2–8.0 m/s. Along all the eastern coast of Middle Caspian, the regime of wind speed is approximately the same. Annual wind speed is about 5.0–6.3 m/s, with the maximum in areas of Fort Shevchenko and Kara-Bogaz-Gol. In South Caspian where strong winds are observed seldom, annual wind speed makes 3.0–4.5 m/s.

Average annual air temperature in the northern part of the sea equals to 8–10°, in the middle part, it equals to 11–14°, and in the southern part, 15–17°. For the whole

sea, on the average, it equals to 13.1° . The average air temperature above all the water area in July–August is within the limits of $24\text{--}26^{\circ}$ (Gidrometeorologija, 1992).

Hydrological regime of the sea and its coastal zone

The basic role in the formation of a hydrological regime of the Caspian Sea is played by river runoff, the climate, and morphometric characteristics (sea depths, bottom relief, and the character of the coast).

Sharply contrast climate and physical-geographical features of northern, middle, and southern parts of the sea are the reasons for essential differences in the hydrological regime of them. The northern part of the sea should be marked out. Shallow North Caspian is most subjected to the influence of sweet river waters inflow and sharp fluctuations of seasonal air temperatures. Each winter, the sea here is covered by ice.

The general circulation of waters of the Caspian Sea (horizontal and vertical) is created by cumulative influence of wind, the density field, rejecting forces of rotation of the Earth, and convection. The resulting system of currents of the Caspian Sea, as well as drift and geostrophic currents taken separately, has the character of circulations of different signs.

Wave regime of the sea and its coastal zone

The Caspian Sea belongs to the seas with rough waving. Development of waves of big height is promoted by strong storm winds of northern and southern directions and great meridional extent of a water body. The maximal wave heights in the open sea during strong storm in 1954 reached 14 m.

Storm processes are especially intensive in autumn and winter in North Caspian. In the middle part, the most intensive waving is observed under northwestern winds (in Apsheron region, the maximal wave height with recurrence of 1 times per 50 years can reach 15–17 m). To the northeast from Makhachkala, waving is stronger under southeast winds.

Water balance and the sea level – long-term fluctuations

For the period of instrumental observations from 1830 until present time, the amplitude of fluctuations of the sea level has made 3.8 m; the highest standing of the level was registered in 1882, which was -25.2 m; the lowest one – in 1977 – was -29.0 m. In 1995, the average annual level was equal to -26.51 m. Three time periods can be distinguished, having sharply different regimes of the sea level: the first is prior to the beginning of 30th years of the previous century; the second, up to 1977; and the third, from 1978 till now. The first of these periods that lasted for about a hundred years had the most steady characteristics of the level with annual average value being nearby -26.1 m (Figure 2).

For the second period, sharp enduring falling of the sea level is characteristic. Since 1930, the sea levels dropped annually, and until 1941, annual decrease of the level made 16 sm. Later, the level on the whole continued falling replaced by small rises in some years. The general decrease of the sea level during the whole second period has made 2.8 m. In 1977, the sea level reached the lowest mark for all the period of instrumental measurements (-29.0 m).

For the third period, since 1978, continuous (during 18 years) rising is characteristic at an intensity of about 14 sm a year. The rising of the level in 1995 made 2.5 m. Fluctuations of water balance components of the sea lead to seasonal and long-term fluctuations of the water level of a closed water body. Water balance equation for the Caspian Sea in the most simple form is written as follows:

$$P + Q - E - Q_{KB} = w, \quad (1)$$

where P is the precipitation on the sea surface, m^3/year , Q is surface and underground inflow to the sea, m^3/year , E is the evaporation from water surface of the sea, m^3/year , q is the runoff into Kara-Bogas- Gol, m^3/year , w is the change of water volume in the sea, m^3/year .

Caspian Sea, Figure 2 Fluctuations of The Caspian Sea level over the period of instrumental observations.

In the receipt part of water balance, the basic role is played by river runoff, especially that of Volga making approximately 80% of the total water inflow into the sea. Available data of long-term instrumental observations show that fluctuations of river runoff are characterized by grouping of high-water and low-water years. Such series (grouping) can proceed for up to several decades, significantly determining fluctuations of sea water level.

The volume of underground runoff into the sea is estimated on the basis of special hydrological researches, it makes no more than 3–6 km³ per year, which is only about 1/1,000 of the evaporation losses from the whole Caspian Sea. Outflow of sea water into Kara-Bogaz-Gol is determined basically by a difference of water levels between the sea and the gulf.

The major element of the expense part of water balance of the sea is evaporation from water surface. Direct measurements of evaporation from the sea are impossible. Estimation methods and special in situ researches allow estimating evaporation using standard meteorological observations from coastal and island stations, by ships, and sea platforms. The average layer of an annual evaporation makes 960 mm of water.

Principal reasons for sea level changes are climatic ones. Interannual changes of humidification of the watershed, including water area of the sea, cause changes in river runoff volumes, in amount of precipitation, and in evaporation from the sea surface.

The outflow from the sea into the Kara-Bogaz-Gol Gulf impacts essentially on sea level fluctuations. The water discharge into the gulf depends on the difference between the sea level and the gulf water level. As much as 20–25 km³ of water per year can be evaporated from the gulf water surface. In 1980, a dam between the sea and the gulf was built for the purpose of sea level stabilization. Due to this action, the outflow into the gulf was stopped, and the gulf was dried up completely during several years. In 1992, the dam has been destroyed to prevent the sea level growth, and the water exchange between the sea and the gulf has been restored.

Modern estimations of the sea water balance are following: the river water inflow is 315 km³ per year, the visible evaporation (evaporation minus precipitation) is equal to 0.75 m per year.

Seasonal fluctuations of the sea level

Depending on rivers runoff and evaporation from water surface, intra-annual (seasonal) fluctuations of the level are characteristic for the sea. The magnitude of fluctuations is defined basically by river runoff which is noted for its great seasonal variability. From April till June, due to river runoff, the basic rising of sea level takes place, and in June, the maximum is usually observed. Since July–August when river runoff is considerably reduced and evaporation increases, the sea level drops to the winter minimum in December (Middle and the South Caspian), in January–February (North Caspian). Annual average

amplitude of seasonal fluctuations of the sea level equals to 30 sm, but in North Caspian, it reaches 40 sm.

Short-term changes of the sea level

Short-term fluctuations of the sea level are tidal (periodic), seiche, baric, and set-up and set-down fluctuations.

Seiches characterize natural fluctuations of a sea level as a closed reservoir. The measured periods of seiche make 2.7–3.0, 4.4–4.7, and 9.0–9.5 h; some of them are observed only at the eastern coast (9–9.5 and 24 h), seiche with the period of 24 h having breeze character. In shallow northern part of the sea during the passage of cyclones, level fluctuation of the synoptic period (from 4 to 12 days) is observed.

Windwave changes of the sea level being often observed during the development of severe storms are the most dangerous. In North Caspian, because of extensive shoals favorable conditions develop for the formation of significant set-up and set-down level fluctuations not exceeding 10–20 cm in deep parts of the sea. In the coastal zone of the western part of North Caspian, frequent continuous southeast and east winds are the reasons for annual set-up from 0.5 m up to 1–1.5 m and for set-down of the same height at the eastern coast. Extreme values of the sea level deviations from static horizon before a storm can reach 4.5 m. The shore during the maximal development of such a set-up has been flooded on 25–50 km.

Long-term forecasting of long-term fluctuations of the sea level

The forecast of water level fluctuations of the Caspian Sea is the most complicated geophysical problem. It demands knowledge of mechanisms of the origin of long-term fluctuations of the climate and the river runoff. Poor predictability of long-term dynamics of hydrometeorological processes today allows estimating only probability characteristics of future fluctuations of the Caspian Sea level.

The water balance mechanism of level fluctuations of a closed water body consists in the following. The water received by a water body in the form of river inflow and precipitation, is spent basically on evaporation. When total water inflow exceeds evaporation, the level of a water body grows, that leads to the increase of the area of the water surface and, accordingly, to the growth of evaporation. If evaporation exceeds the inflow, the level drops and the evaporating surface decreases. Correspondingly, the evaporation decreases leading to the deceleration of the rate of water level decreasing. As the result, in stationary climatic conditions, the level of an internal closed water body fluctuates around the position adequate to the balance of annual average sizes (volumes) of inflow and evaporation (the so-called level of gravitation) (Krickij et al., 1975).

The problem of the forecasting of a closed water body level is reduced to the probability forecast of processes of river runoff and evaporation and the account of positive

and negative relationships in the system under investigation described by the stochastic differential equation of water balance. Forecast estimations, as a rule, are received by the method of imitating modeling.

Ice regime of the sea

The Caspian Sea is partially freezing water body, and shallow northern part of the sea becomes frozen annually. In the middle part, ice appears along the coasts only during severe winters; in the southern part of the sea ice does not appear.

In winters with normal temperature conditions, ice formation starts in shallow eastern areas of North Caspian in the first half of November. Further, it extends westwards, covering almost simultaneously shallow western area and the Volga beach.

In cold and extremely cold winters, stationary ice is established on the whole water area of North Caspian up to the depths of 20 m. In very warm winters on the greater part of North Caspian, steady freezing does not occur.

The important role in the establishment of ice cover on North Caspian is played by ice drift. Ice drift occurs mainly from east to west and southwest along the edge of the fast ice and along the western coast of the Caspian Sea. The speed of general drift of ice is about 7 km/day. The process of ice cover destruction and clarification in North Caspian proceeds in spring in the direction reverse to that of ice formation – from the south to the north.

Maximal thickness of ice of natural increase as a rule does not exceed 60 sm in the northwestern part of the sea and 90 sm in the northeastern part.

Ice cover in the sea is more often represented in the form of stratifications. Strong winds, especially in an initial stage of ice cover formation, promote to breaking of fast ice and to its intensive motions. At the thickness of ice from 1 up to 30 sm, its repeated stratification and hummocking take place.

The height of hummocks makes 1–2 m; in some places, it reaches 3 m. Hummocks are often allocated in ridges

with the length of from one up to several km and with the width of some tens of meters. Ridges settle down approximately perpendicularly to dominating winds.

In the initial stage of ice cover forming, when the border of young ice extends from the coast up to the depths of 2–3 m, during ice motions, there are formed hummocks sitting on the ground – stamukhas. Stamukhas differ according to time and place of their occurrence, and also by the type of ice they are formed of.

Stamukhas of *autumn origin* have, as a rule, small size in diameter (5–20) and height of 1–3 m. Such stamukhas are formed everywhere in a coastal strip of the sea (from water edge up to the depths of 1–2 m) along northern and eastern coasts of the Caspian Sea.

Stamukhas of winter origin are formed of ice having 20–70 cm thickness, and can reach 100–300 m, sometimes 500 m in diameter and the height of 10 m. The Maximal registered height of stamukha makes 20 m.

Paleogeography of the Caspian sea

Paleogeography of the Caspian Sea in Pleistocene (~800, 000 years) is characterized by sharpness and large scale of fluctuations having led to changes of water environment parameters and replacement of faunistic communities and vegetation that distinguishes the Caspian Sea from open seas (Rychagov, 1997).

According to modern concepts, the contemporary Caspian Sea is now in a deep regressive stage concerned to begin at the end of Pleistocene; since that time, the level of the Caspian Sea did not reach 0 m absolute heights. As a whole, the Caspian Sea in Pleistocene is characterized by higher standing of the sea level.

In Quaternary history of the sea, such transgressive epochs as Bakinian, Early Khazar, and Khvalynian ones can be concerned as the events of the same order; they were separated by deep and long regressive epochs.

The beginning of Pleistocene in the Caspian Sea was marked by rather long (about 100, 000 years) epoch of low standing of the level – *Turkianian Regression*. The sea level went down up to absolute height – 150 m. Some rivers of the southern slope of the Big Caucasus have

Caspian Sea, Figure 3 Fluctuations of The Caspian Sea level over the past 10,000 years (according to Rychagov, 1997).

deepened their valleys up to this depth. All water volume of the Turkianian Basin was concentrated in Southern Caspian and Middle Caspian depressions, between which there was a shallow strait in the area of Apsheiron threshold.

The regression was replaced by large and long transgression which included the middle and the end of early Pleistocene – *Bakinian Transgression*. In the opinion of many researchers, the Bakinian epoch was characterized by two transgressions – Early Bakinian and Late Bakinian, separated by the regression. The level of Late Bakinian Sea hardly exceeded the marks of 5–10 m absolute height.

The second large transgressive basin in Pleistocene history of the Caspian Sea is Middle Pleistocene – *Early Khazar Transgression*, not yielding to the Bakinian one in size and level position. The end of the Khazar stage of development of the Caspian Sea (the middle of Late Pleistocene) was marked by deep regression – *Atelian*. At that time, extensive areas of the Caspian shelf, especially in the north of the Caspian Sea, were drained; there was an intensive incision of rivers (the depth of Volga incut in its estuary part made some tens meters, and within the region of Volgograd, it made 20 m).

Atelian regression was replaced by *Khvalynian Transgression* – the third and the last large increase of the Caspian Sea level that took place in the second half of late Pleistocene. The total area of Khvalynian Sea is estimated to be 950, 000 of k km².

Waters of Khvalynian transgression had drainage into the Black Sea depression. In the opinion of the majority of researchers, the drainage has begun after the level of the Caspian Sea has received the marks exceeding Manych threshold (45–50). Late Khvalynian transgressive stage during the period of its maximal development had a level about 0 m absolute heights. In the north, its waters have occupied significant territory.

Post-Khvalynian Regressive Stage has begun in Early Holocene and is lasting now. It consists of several regressive and transgressive phases and oscillations, such as: Mangyshlak regression, New Caspian transgression, and modern regression including present increase of the level as well (Figure 3).

CHAD LAKE

Jacques Lemoalle¹, Jean-Claude Bader¹, Marc Leblanc²
¹G-Eau/IRD, Montpellier, France
²School of Earth and Environmental Sciences, James Cook University, Cairns, Australia

Introduction

Lake Chad lies in an endorheic basin located in the center of Africa and is on the southern margin of the Sahara in the semiarid Sahel belt. It is a highly variable shallow lake centered approximately on 13°30'N and 14°E (Figure 1). During the last century, its water area has varied between 1,700 and 25,000 km² in accordance with the changes in rainfall over its basin. When dealing with Lake Chad, it is thus necessary to specify the period considered.

The lake belongs to Chad, Niger, Nigeria, and Cameroon. It provides a wealth of natural resources (supporting fisheries, recession cultivation, and rangeland) that are highly attractive to many populations in the region, especially during drought years.

Lake Chad: variability and landscapes

Lake Chad has a long history of wet and dry periods spanning different time scales. During the late Quaternary, the last Holocene lacustrine transgressions, interspersed with dry shorter episodes, occurred between 8,500 and 6,300 BP (when the water level reached up to 325 ± 5 m asl and the lake extent 340,000 km²) and around 3,200 BP (287–290 m asl) (Servant and Servant, 1983; Leblanc et al., 2006a, b).

Over a shorter time scale, during the last millennium, data from sediment analyses and other historical records indicate a similar succession of high (up to 285 m asl) and low levels, with four to five drought periods between 900 and 1900 AD. A very dry period of 25–30-year duration at the end of the fifteenth century has been well documented (Maley, 1993).

Since the beginning of the nineteenth century, European explorers have described Lake Chad either as a very large body of water or an extensive partly dried marsh. A classification into three main states for the lake was proposed by Tilho (1909–1910), who showed that the large variations in lake level and landscapes were directly related to rainfall changes in its basin:

- The *Large Lake Chad* spans across 24,000 km² of open water with a limited coastal sand dune archipelago and occasional slight overflow toward the northeast through the Bahr El Ghazal at the extreme east of the lake which leads to the Bodele depression, some 500 km to the NE

Chad Lake, Figure 1 The location of Lake Chad in Africa at the southern border of the Sahara.

and some 120 m lower. This Large Chad state has occurred only for short periods during the last century and for the last time in the mid 1950s.

- The *Normal (intermediate) Lake Chad* is a single body of water covering about 18,000 km², at an intermediate water level of about 280–282 m asl, with an archipelago of some 2,000 dune islands and a limited marshy vegetation on the shores (Figure 2). The lake is divided into two main basins separated by a shallow and narrow belt, the Great Barrier. On the northeast side of both basins, the lake is bordered by an erg of ancient dunes, the altitude of which progressively decreases along a northeast-southwest axis. This creates an archipelago of sandy islands, with a decreasing altitude toward the open waters of the two basins. In the Normal state, the total lake is composed of an extended archipelago and large areas of open water covering about 4,000– 6,000 km² in each basin. The increase in total inundated area is about 2,000 km² for a change in water level of 1 m around 281 m asl, with the northern basin having much steeper shores (Figure 3). The depth encountered in the central zones of the two basins is about 5.3 m in the northern basin and 2.7 m in the southern basin. At water levels of 280 and 282 m asl, the mean depth is 2.1 and 3.5 m, respectively (Bader et al., 2011). The Normal Lake Chad state occurs when the annual discharge from its main tributary, the Chari River, is comprised between 34 and 43 km³/year. The last shift from Normal to Small Lake Chad occurred in 1973–1975 (Figure 4).
- The *Small Lake Chad* is made up of different separated bodies with a permanent open water pool of about 1,700 km² at a maximum altitude of 280–281 m asl in front of the delta of the Chari River. The northern basin may completely dry up or be seasonally inundated. Permanent or seasonal marshes ranging from 2,000 to 14,000 km² cover the northern basin of the lake and

Chad Lake, Figure 2 The main regions of the Normal Lake Chad and the location of the main sill (Great Barrier) between the southern and northern basins (Landsat MSS mosaic in January 1973. Modified from Lemoalle 1991).

Chad Lake, Figure 3 The relationship between water level and lake surface area. When the level is below ~ 280 m asl, the lake is split into two separate basins: A_s and A_n are the lake areas in the southern and northern basins, respectively. (From Bader et al., 2011).

parts of its southern basin and archipelago (Leblanc et al., 2007; Leblanc et al., 2011). This Small Lake Chad occurs when the annual discharge from the Chari River is below $34 \text{ km}^3/\text{year}$. It has been observed for short periods around 1905–1907, 1915, 1940, and since 1973. The northern basin of the lake receives no water when the annual Chari River discharge is less than 15 km^3 (Table 1).

From 1957 to 2008, the lake has been in a Small state for 69% of the time and in a Normal or Large state for 31% of the time (Bader et al., 2011).

Hydrological functioning and water balance

Except during Large Lake Chad periods, the lake has no surface outflow. River and rainfall inputs are offset by evaporation losses, some seepage, and by volume and area fluctuations according both to seasonal and annual variations of the inflows. As these inflows are closely associated with rainfall over the basin, the lake is highly sensitive to climate variability. In natural conditions, it is a good indicator of climate fluctuations, but it may also react rapidly to man-made changes in its water budget.

Rainfall follows the displacement of the Intertropical Convergence Zone (ITCZ), which moves northward over the active part of the basin from February to August. Since the beginning of the 1970s, the ITCZ has not been moving as far north as before; hence, a lower rainfall over the basin.

A period of above average rainfall from 1950 to 1967 over the West African Sahel was followed by below average rainy seasons after 1970, with a succession of harmful droughts that peaked in 1972, 1973, and 1984 (L'Hôte et al., 2002; Figure 5). Over the Chari-Logone Basin, annual rainfall has decreased by about 150 mm from $1,095 \text{ mm/year}$ (1950–1967) to 932 mm/year (1972–2006) with a north-south displacement of the rainfall gradient of 150 km (Climatic Research Unit, 2003). A $\pm 10\%$ change in mean annual rainfall over the basin results in

Chad Lake, Figure 4 The water level in the two main regions of Lake Chad during the transition from Normal to Small lake. During a Small Chad state, at least two different water levels are needed to describe the lake. The locations of the gauges are given in [Figure 2](#).

Chad Lake, Table 1 The main characteristics of the different states of Lake Chad

Lake Chad	Small	Normal	Large
Chari River discharge (km ³ /year)	10–34	40	45
Water level (m asl)	Several levels	280–282	>282.3
Number of water bodies	several	one	one
Total lake area (km ²)	2,000–14,000	15,000–19,000	20,000–25,000
North basin inundated area (km ²)	0–8,000	9,000	10,000
Landscape	Marshes	Dune islands	Open waters
Aquatic vegetation	+++	++	+

a $\pm 30\%$ change in the annual discharge of the Chari River, the main tributary to the lake, which has also been lowered as follows (data from Direction des Ressources en Eau et de la Météorologie, DREM, Chad) ([Figure 6](#)):

- Period 1960–1969 – 41.0 km³
- Period 1970–1979 – 31.1 km³
- Period 1980–1989 – 16.6 km³
- Period 1990–1999 – 20.4 km³
- Period 2000–2006 – 22.0 km³

This decrease in the discharge of the Chari River is the main reason for the decline in Lake Chad water levels and the shrinking of surface area from a Normal to a Small lake.

The water budget of Lake Chad has been studied by a number of authors (see Olivry et al., 1996). Mean values for the period 1954–1969 of Normal Lake Chad are given in [Table 2](#). The main input to the lake is the seasonal discharge of the Chari River (41.7 km³/year or 82.3% of total inputs), supplemented by direct rainfall (14% of total inputs) and inflow from the other small tributaries, El Beid and Komadugu Yobe (1.43 and 0.49 km³/year, respectively, or 3.6% of total inputs). The losses result mainly from evaporation (95.5%) and seepage out of the lake (4.5%). The seepage may, however, change in direction, seasonally or from year to year, according to the trend in the change of the water level.

The hydrology of the Small lake is controlled by the Great Barrier, the main sill separating the two main basins ([Figure 2](#)). Its altitude is close to 279.3 m, but it is covered with dense vegetation acting as a break to the circulation of water (the Great Barrier extends more than 40 km between the two basins). The water from the Chari River feeds the southern basin and overflows over the Great barrier only when the flood is sufficient.

Starting from the seasonal low level in July or August in the southern pool, an increase in level occurs with the input of the flood from the Chari River until a level of 279.5–280 m asl is reached in December. If this level is reached, some overflow occurs toward the northern basin of the lake through the Great Barrier. An annual discharge of the Chari River exceeding about 15 km³/year is needed for this overflow to occur. The water budget of the Small Chad is quite complicated because of the separate behavior of the different basins. A hydrological model has been developed to simulate the water level and extent in these basins (Bader et al., 2011).

While the annual cycle in the southern basin during a Small Chad period is fairly similar from year to year, it

Chad Lake, Figure 6 Total annual discharge of the Chari River at N'Djamena (a hydrological year os from May year i to April year $i + 1$). (Data from Olivry et al. (1996) and DREM (Tchad)).

Chad Lake, Table 2 Mean values for the components of the water budget of a Normal Lake Chad (1954–1969). Values expressed as water height (mm/year) over the lake surface area (From Vuillaume, 1981)

Component	Unit	Normal Lake Chad
River inputs	mm/year	+1946
Direct rainfall	mm/year	+329
Evaporation	mm/year	−2170
Net seepage	mm/year	−102

is highly variable in the northern basin. The lake has decreased in level and area between 1965 and 1973. The process continued during 1973–1976 when the lake split into different water bodies and with the first total desiccation of the northern basin. Since 1976, Lake Chad has been in a new equilibrium of Small state (Figure 7). Contrary to news reports in the press or on the web (e.g., NASA, 2003), Lake Chad is, at the time of writing (2010), neither shrinking,

disappearing nor dying. It is a Small Lake Chad, as it has been several times in the past prior to recovering Normal or Large Lake Chad water levels.

Water chemistry

Contrary to most closed lakes in a semiarid climate, the lake water remains relatively fresh. In the Normal Lake Chad state, the water electrical conductivity is about 60 $\mu\text{S}/\text{cm}$ (TDS about 40 mg/L) at the delta of the Chari River and increases as the water progresses into the lake to the east and north. It is usually about 120 $\mu\text{S}/\text{cm}$ (TDS = 80 mg/L) at Bol and reaches 1, 200 $\mu\text{S}/\text{cm}$ (TDS about 900 mg/L) around N'Guigmi (see Figure 2). This low salinity has been explained by the combination of two processes: (1) in the water, the cations are mainly involved in chemical equilibria with precipitation of carbonates (Ca and Mg), adsorption on suspended clay particles, and possible neoformation of clay, (Carmouze, 1983), and (2) some of the most concentrated water, close to the lake shores, is exported by seepage. A small volume of seepage water thus exports a large quantity of salt which is collected as natron (sodium carbonate/bicarbonate) further inland in the small inter dune depressions.

The processes acting during the Small Lake Chad state have been less studied, but the increased CO_2 partial pressure associated with the vegetation does not allow for the same Ca and Mg precipitation.

In the open water areas, Lake Chad is polymictic, with usually a nycthemeral cycle.

Flora and fauna

The aquatic vegetation comprises mainly *Cyperus papyrus*, *Phragmites australis*, *Typha australis*, the tall leguminous *Aeschynomene elaphroxylon*, *Echinochloa sp.*, and other smaller plants such as *Ipomea spp.*

Chad Lake, Figure 7 The water level as monitored at the Bol gauge (Data from ORSTOM and DREM). Since March 1973, the Lake has split into basins of differing water levels and cannot be described by a single water level. The level from March 1979 to May 1984 has been calculated from Kirinowa levels using a correlation between the two stations.

The submersed vegetation comprises mostly *Potamogeton* and *Ceratophyllum* and does not cover large areas. Up until now, water hyacinth (*Eichhornia crassipes*) has not been present in the lake. Large quantities of *Pistia stratiotes*, *C. papyrus*, and *A. elaphroxylon* are found in the southern basin of the Normal lake but not in its northern basin, maybe because of the higher water salinity (Iltis and Lemoalle, 1983).

The distribution of these species is highly dependent on the changes in water level. In the first half of 1973, the riparian band of vegetation almost disappeared when the water level receded, but later covered most of the southern basin after the first rains in the same year. The northern basin became completely devoid of vegetation when it dried up in 1975. Later, a very dense forest of *Prosopis juliflora* rapidly covered all of its central part in the 1980s while the basin was dry. When the northern basin became inundated again, most of these trees died, and the usual aquatic vegetation developed over large areas.

The fish community in the lake is primarily riverine. It is dependent on the hydrologic conditions in the floodplains of the lower Chari, Logone and Komadugu Yobe Rivers, together with the lake proper. Many of the fish migrate for reproduction either within the lake itself or from the lake to the river system. A total of 127 fish species belonging to 27 families have been recorded in the lake, many being shared with the Nile, Niger, and Senegal Basins (Lévêque and Paugy, 1999). There are no endemic fish species to the basin.

In the large marshes of the Small Lake Chad, and especially in the northern basin, only the few species that can sustain the frequent lack of oxygen in the water remain: *Heterotis niloticus*, some tilapia, and *Clarias spp.* make the main commercial catch under these conditions.

Lake Chad and the wetlands in its basin are a main feature for migratory Palearctic and Afrotropical birds. Some 70 species make stopovers each year, including numerous garganey (*Anas querquedula*), pintail (*A. acuta*), and the ruff (*Philomachus pugnax*). Other numerically

important species include grey and purple herons, large flocks of crested cranes, the black winged stilt (*Himantopus himantopus*), and the glossy ibis. Pelicans (*Pelecanus onocrotatus*) and shags (*Phalacrocorax africanus*) may be seen in numbers in the delta of the Chari River and in the southern basin. Caspian and gull-billed terns (*Sterna tschegrava* and *S. nilotica*) are mainly fish eaters, while the whiskered and white-winged black terns (*S. hybrida* and *S. leucoptera*) have a mixed diet of fish and insects. The large emergence of chironomids or Mayflies often leads to considerable aggregations of white-winged black terns.

A few hippopotamuses (*H. amphibius*) may be seen near the Chari River delta, but in much smaller numbers than before the 1973 drought when many died because of lack of food.

The Nile monitor (*Varanus niloticus*) has benefited from the development of the marshes during the Small Lake Chad. It is quite commonly seen but subject to a heavy toll for its skin which is exported.

Under the auspices of the Lake Chad Basin Commission, Lake Chad is now registered in the Ramsar Convention for the protection of the aquatic habitat (Ramsar, 2010).

The use of natural resources

Rain-fed agriculture and livestock are the main food-producing activities in the semiarid African Sahel. A water body in such an agroclimatic region is very attractive for the surrounding populations, especially during drought periods. Since the 1973 and 1984 droughts, a large population has gathered around the lake for recession cultivation on the rich lake sediments, livestock keeping, and fishing (Kolawole, 1988).

When the Chari River flood is sufficient to inundate a large part of the northern basin of the lake, the resource availability of a "Small Lake Chad" is at its maximum in both basins and probably larger than during the Normal lake state. But the rainfall variability is such that, in some years, the river flood is insufficient to feed the northern basin of the lake which remains dry. The population in

the northern part of the lake then has to move to find their living, while the resources in the southern basin remain stable.

The heads of State of the Lake Chad Basin have thus given mandate to the Lake Chad Basin Commission to study the feasibility of a water transfer from the Ubangui River in the Congo/Zaire Basin, which would allow for more sustainable water availability in Lake Chad and for the surrounding large irrigation projects. A feasibility study has been launched in 2009.

Irrigation

The South Chad Irrigation Project (67,000 ha) and the Baga Polder Project (20,000 ha), on the Nigerian shore of the lake, were inaugurated respectively in 1979 and 1982. Their full operation would have needed 2.5 km³ of water per year, but the lake recession did not allow for the irrigation of more than 7,000 ha in the first years of operation before a complete halt (Thambyahpillay, 1983; Hollis, 1990).

Many of the reservoirs and irrigated areas (Maga dam in Cameroon, polders in Lake Chad, and reservoirs on the Komadudgu Yobe system in Nigeria) use some water which would naturally feed floodplains, where most of the water is lost through evaporation. Although this is detrimental to the floodplains ecology and their natural resources, the net water abstraction at the basin scale remains limited.

Currently, and with the available data, it is estimated that less than 200 Mm³ are abstracted annually from the Chari-Logone system upstream of N'Djamena where discharge is measured (Rép. du Tchad-PNUD, 2003). The gross water uptake in the lake for the polders irrigation scheme is 75 Mm³, but this is less than what would have evaporated from the lake surface had they not been implemented.

The net uptake for irrigation in the Lake Chad Basin, including the reservoirs on the Komadugu Yobe Basin, therefore amounts to approximately 200–300 Mm³/year. This value is much lower than previous estimates and does not substantially contribute to the present low water levels of the lake as reported elsewhere (Coe and Foley, 2001).

Contrary to the Aral Sea, the Small Lake Chad status largely results from the change in rainfall over the basin as explained above.

Threats and priorities

The models presently available on global climate change do not allow for reliable estimates of trends in the rainfall over the Lake Chad Basin during the coming decades. It is thus not possible to predict whether the natural Chari River discharge will decrease or increase as a result of climate change. Future human development in the basin may increase water abstraction through new or rehabilitated irrigated schemes around the lake or along the Chari and Logone Rivers.

It is not appropriate to say that Lake Chad is presently dying. The lake hydrology and landscapes have completely changed in 1972–1973 with the shift from

a “Normal” to a “Small” Lake Chad. But since then, the lake status has remained fairly stable, especially in the southern basin.

With the increasing population, a future reduction of the rainfall would put an unsustainable pressure on the natural resources of the basin, of Lake Chad itself, and its associated floodplains and surroundings. It is thus necessary to further improve our understanding and monitoring of surface and groundwater resources availability so that food supply and ecosystem services are guaranteed and become less vulnerable to rainfall variability.

Introduction

Geological evidences indicate that the Chilika Lake was part of the Bay of Bengal during the later stages of the Pleistocene period (Pascoe, 1964). Abrupt changes in the morphology of the coast along north of the lake; strong winds shifting sand to the shore; longshore drift (littoral

drift) and the presence or absence of strong river and tidal currents in different areas are the reasons attributed to the growth of the spit. A 60-km (37 miles)-long barrier beach called Rajhansa, formed by northerly currents in the Bay of Bengal, resulted in the formation of this shallow lake and forms its eastern side. It is a shallow brackish-water inshore lake, connected to the Bay of Bengal through a narrow mouth. Chilika Lake is bordered between the sea and mountains. Formation of a barrier spit near Palur due to littoral drift and creation of a sand bar along the eastern shore have transformed the lake gradually to a shallow lagoon. Presently, the sea is connected with the lake near Satapada through a number of shoals, sand spits, sand bars, openings of shallow depth, and a narrow channel. The presence of these features considerably reduces tidal flow in and out of the lake. In the past, discharge of sediment by the tributaries of the Mahanadi River made the lake shallower, and subsequently, the lake was separated from the sea after the formation of the spit (Krishnan, 1968). The lake is continuously becoming shallow; sandbanks and a number of islands are visible just above the surface because of the discharge of silt and sediment by the rivers Daya, Bhargavi, Makra, and Nuna. About 1.6 million metric tons per year of sediment is deposited in Chilika Lake by rivers and several streams. Some of the rivers are tributaries of the Mahanadi River, and others are streams joining the lake. Water level in the lake fluctuates seasonally and during high and low tides. Similarly, maximum area of the lake experiences submergence and emergence every year.

Geography and topography

Chilika (19° 28'–19° 54' N; 85° 06'–85° 35' E), the largest subelliptical brackish-water lagoon in Asia (Figure 1) and one of the largest tropical lagoons in the world, has been marked as Category I of the marine protected areas and designated as a Ramsar site on the Ramsar Convention of Wetlands in 1981. The western and southern margins of the lake are fringed by the Eastern Ghat hill range. The north shore of the lake is part of Khordha district, and the western shore is part of Ganjam district of Orissa. The shallow water body (average depth 2 m) is about 65 km in length, spreading from northeast to southwest parallel to the coastline with a variable breadth reaching 20.1 km. The lagoon spreads over an area of 950 km² during summer, which swells up to 1,165 km² during monsoon (Siddiqui and Rama Rao, 1995). The lagoon is connected with the Bay of Bengal near Satapada by means of an artificial opening made in September 2000 before which a 24-km-long narrow and curved channel running parallel to the coast was joining with the Bay of Bengal near Arakhakuda. During winter (November–January), a large portion of this lagoon remains submerged and acts as a wetland, which also serves as breeding and nesting grounds for millions of migratory bird species. High evaporation from the shallow water body during summer (April–June) and a large inflow of freshwater through

Chilika Lake, Figure 1 Chilika Lake showing the catchment area and connection to the Bay of Bengal through the new mouth.

various rivers and rivulets at the northern end of the lagoon during the monsoon (July–September) and post-monsoon (October–November) seasons significantly influence the water spread area of the lagoon (Mohanty et al., 1996). The catchment area of the lagoon is 4,406 km², in which 68% is constituted by western catchment and 32% by the Mahanadi delta. The total inflow of freshwater has been estimated at 14, 331 million cubic kilometers per year (Panigrahi et al., 2009). The three distributaries of Mahanadi River, namely, Daya, Bhargavi, and Nuna, account for 55% of the total inflow whereas the streams/rivulets from the western catchment contribute the rest 45% (Annon, 2003). Over the years, the lake environment is under severe stress due to siltation, changes in salinity, weed infestation, aquaculture activities, decline in fish yield, loss of biodiversity, etc. A severe cyclonic storm in 1999 caused dramatic change in the biotic communities in the lake.

Floral diversity

Phytoplankton

Phytoplankton community of Chilika Lagoon consists of a mixture of marine, brackish-water, and freshwater taxa, mainly represented by four groups of algae – diatoms (Bacillariophyceae), dinoflagellates (Pyrrophyceae and Dinophyceae), blue-green algae (cyanobacteria), and

green algae (Chlorophyceae). A maximum number of 128 species of phytoplankton have been reported from the lake (Panigrahi et al., 2009). Diatoms are the dominant group and represented by 79 species (41 centrales and 38 pennales). The dinoflagellate population is represented by 13 species. Blue-green and green algae (with 9 families and 15 genera) are represented by 18 species each. Some of the recent dominant taxa of phytoplankton, including those distributed throughout the lagoon as well as those in the more freshwater-influenced northern sector and the saline-water-dominated outer channel area, are reported elsewhere (Panigrahi et al., 2009). The phytoplankton assemblages of the lagoon are dominated by diatoms, certain dinoflagellates, and blue-green algae during summer season when the salinity in most parts of the lagoon is about 17 psu. However, during the winter season, the plankton flora is mainly represented by blue-green and green algae. Phytoplankton species composition also varies spatially between seasons. In general, the outer channel area has higher species diversity than the other regions. Diatoms dominate the species composition in the entire lagoon except for the northern region. Dinoflagellates are known to occur frequently in the outer channel area and in the southern region of the lagoon. Northern and central regions had overwhelming numbers of blue-green and green algae. Patnaik (1973) had

reported that the phytoplankton assemblages in the Chilika Lagoon consisted of 54% diatoms, 44.7% blue-green algae, 0.8% dinoflagellates, and 0.6% green algae. The available literature on the lagoon before inlet opening indicates a high degree of variability in phytoplankton composition and density. Biswas (1932), Roy (1954), Patnaik (1973), Patnaik (1978), Panigrahy (1985), Raman et al. (1990), and Adhikary and Sahu (1992) reported taxon richness of 22, 33, 57, 21, 82, 97, and 28, respectively.

Macroalgae and higher plants

The northern and central part of the Chilika Lagoon is densely covered with macrophytes which have a cyclic growth. They grow luxuriantly in the late monsoon and post-monsoon periods and start decomposing in the beginning of summer, with increase in salinity (Panigrahi, 2006; Pal and Mohanty, 2002). The cyclic growth and decomposition of aquatic weeds have been significantly influencing the oxygen saturation of the lagoon water. Hence, levels of DO increase during post-monsoon period due to the photosynthetic release, and its decrease has been noticed when they start decomposing in the summer. Even though there is no rocky intertidal region on the coastline, the rocky islands of Chilika Lake provide home for luxuriant growth of some green, brown, and red algae. The most prominent among them is the agarophyte *Gracillaria verucosa* that serves as a source of agar-agar. Mitra (1946) had estimated that about 4–5 t of *Gracillaria* could be harvested per annum from this lake. The growth of seaweeds in this lake however has considerably declined due to the problem of siltation and salinity reduction in the lake water in the subsequent years.

Recent surveys revealed that an overall 726 species of flowering plants belonging to 496 genera and 120 families are present in and around the Chilika Lake. This represents about one-fourth of the vascular plant species of the Orissa state. Fabaceae is the most dominant plant family followed by Poaceae and Cyperaceae. Certain species were found to be characteristic to specific islands. The flora is predominantly of aquatic and sub-aquatic plants. The species reported are from the families Leguminosae, Poaceae, and Cyperaceae and endemic *Cassipourea ceylanica* along with five species of seagrass. Wild plants of horticultural importance and interesting plant groups such as insectivorous plants, epiphytes, parasites, and lithophytes are also found in the lake environment. Mangrove associates, such as *Aegiceras corniculatus*, *Excoecaria agalloch*, *Salvadora persica*, *Pongamia pinnata*, *Colubrina asiatica*, *Capparis roxburghii*, *Macrotyloma ciliatum*, and many others, are found in abundance.

Faunal diversity

The lake harbors a rich faunal diversity. In total, 323 fish species, 24 mammals, and 37 species of reptiles and amphibians have been reported. The rare and threatened animal species identified in the lake milieu are green sea turtle (endangered), dugong (vulnerable), Irrawaddy

dolphin (vulnerable), blackbuck (near threatened), spoon-billed sandpiper (critically endangered), limbless skink, and fishing cat (endangered).

Zooplankton

Zooplankton studies in the Chilika Lake, in fact in India, started in early twentieth century by Sewell (1913) followed by Annandale and Kemp (1915). Subsequently, observations were made by Devasundaram and Roy (1954), Jhingaran (1963), and Mohanty (1975). Recent observations have shown a significant spatial and temporal variation in zooplankton species composition, population density, and relative abundance. Zooplankton density in Chilika Lagoon ranges from 1740 to 10370 individuals m^{-3} while the biomass values range from 1.72–3.30 $g\ m^{-3}$ (Naik et al. 2008). Copepods, chaetognaths, cladocerans, mysids, lucifers, euphausiids, siphonophores, and sergestids are the dominant groups observed in the lake waters. Copepods alone contribute nearly 70% of total density. The distribution of zooplankton is found to be significantly influenced by salinity variations in the lake.

Fishery

The 323 species of fishes found in the lake involve 261 fin-fish species, 28 prawns, and 34 crabs out of which 65 species breed in the lake (Chilika Development Authority, 2008). Of these, 27 fishes and two genera of prawns are freshwater species. For centuries, fisher folk evolved exclusive rights of fishing through a complex system of partitioning the fisheries of the lake, harvested the lake in a relatively sustainable fashion and developed a large range of fishing techniques, nets, and gear. Butter catfish and *Wallago attu* are the most common types of fish found in the lake. Eleven species of fish, five species of prawn, and two crab species are commercially important. The commercially important prawn species are giant tiger prawn, *Penaeus indicus* (Indian white shrimp), *Metapenaeus monoceros* (speckled shrimp), *Metapenaeus affinis* (pink prawn) and *Metapenaeus dobson* (Kadal shrimp). Mangrove crab is the most important commercial crab available in the lake. Fish landings in the lake, which fluctuated widely in the past, have recorded a remarkable recovery after the opening of the new mouth and dredging of silt-choked old mouth Magarmukh in 2000–2001. This has been attributed to better intermixing of the tidal influx from the sea and freshwater inflow from rivers. Against an all-time lowest landing of fish and prawn of 1,269 t (1,399 short tons) in 1995–1996, the all-time high is reported to be 11,878 t (13,093 short tons) during 2001–2002, resulting in an estimated per capita income for the fisher folk of Rs 19,575 (about US\$392) during that year (Chilika Development Authority, 2008).

Dolphins

The Irrawaddy dolphin present in the Satapada area of the Chilika Lake has been attracting tourists not only from India but also from all over the world. The Irrawaddy

dolphin (*Orcaella brevirostris*) is the flagship species of Chilika Lake. Chilika is the only home to Irrawaddy dolphins in India and one of only two lagoons in the world that are home to this species (Sutaria, 2007). It is classified as critically endangered in five of the six other places it is known to live (Cetacean Specialist Group, 1996). A small population of bottlenose dolphins also migrates into the lagoon from the sea. Chilika fishermen say that when Irrawaddy dolphins and bottlenose dolphins meet in the outer channel, the former get frightened and are forced to return toward the lake. Some Irrawaddy dolphins used to be sighted only along the inlet channel and in a limited portion of the central sector of the lake before the opening of the new mouth. After the opening of the new mouth at Satapada in 2000, they are now well distributed in the central and the southern sector of the lake. The number of dolphins sighted has varied from 50 to 170. A 2006 census counted 131 dolphins, and the 2007 census revealed 138 dolphins. Out of the 138 dolphins, 115 were adults, 17 adolescents, and six calves. Sixty adults were spotted in the outer channel followed by 32 in the central sector and 23 in the southern sector (Das, 2008).

Birds

Chilika Lagoon receives thousands of avian guests coming from faraway places like Siberia during winter months. The presence of such wonderful birds adds to the bounty of the amazing coastal ecosystems along Orissa, for which millions of tourists come here to witness this unique phenomenon of nature. Chilika Lake is the largest wintering ground for migratory birds on the Indian sub-continent. It is one of the hotspots of biodiversity in the country. Some species listed in the IUCN Red List of Threatened Species inhabit the lake for at least part of their life cycle. White-bellied sea eagles, graylag geese, purple moorhen, jacana, herons and flamingos, egrets, gray and purple herons, Indian roller, storks and white ibis, spoonbills, brahminy ducks, shovellers, and pintails are some of the important species found here. According to a survey, 45% of the birds are terrestrial in nature, 32% are waterfowl, and 23% are waders. The lagoon is also home to 14 types of raptors. Migratory waterfowl arrive here from as far as the Caspian Sea, Baikal Lake, and remote parts of Russia, Mongolia, Lakah, Siberia, Iran, Iraq, and Afghanistan and from the Himalayas. In 2007, nearly 840,000 birds visited the lake, out of which 198,000 were spotted in Nalbana Island. On January 5, 2008, a bird census involving 85 wildlife officials counted 900,000 birds of which 450,000 were sighted in Nalabana. Removal of invasive species of freshwater aquatic plants, especially water hyacinth, due to restoration of salinity, is a contributing factor for the recent increasing attraction of birds to the lake.

Environmental status

The lagoon has several hydrological influences. Important among them are (1) drainage from unregulated degraded catchment basin lying on the western and southern

boundaries, (2) silt-borne freshwater discharges from the distributaries of Mahanadi River, and (3) exchange of lagoon water with Bay of Bengal. Changes in the strength and nature of these hydrological connections can have drastic and potentially unexpected consequences for the lagoon. The spatial and temporal salinity gradients caused due to freshwater flow from the riverine systems and seawater intrusion under tidal influence give it the characteristics of an estuarine ecosystem.

There has also been a general increase in the pollution load from agricultural waste, aquaculture, and domestic sources from the drainage basin. The western catchment contributes an average of $\sim 536 \text{ m}^3 \text{ S}^{-1}$, and the distributaries of the Mahanadi River (Daya, Bhargavi, and Nuna rivers) contribute an average of $\sim 850 \text{ m}^3 \text{ S}^{-1}$ (Patnaik, 2002). Furthermore, the introduction of prawn culture ("gheri" or bund fishing) in 1991 led to various changes in hydrology and sediment transport processes, mainly as a result of the use of split bamboo and very fine mesh nets encircling the culture area, which prevented free sediment flow. The amount of sewage discharged to the lagoon from the capital city Bhubaneswar was observed to be ~ 550 million liters day^{-1} , along with a huge amount of untreated domestic wastewater from the 141 villages in and around the lagoon. Analysis of the capital city's wastewater indicates suspended solids concentrations of roughly 275 mg l^{-1} and an average biochemical oxygen demand of 110 mg l^{-1} (Panigrahi et al., 2009), far above the permissible limit of 20 mg l^{-1} (Orissa State Pollution Control Board, unpublished data, 1998). The siltation, reduced salinity, increased pollutant load from the catchment basin, and restricted outflow of lagoon water (to the sea) resulted in the rapid growth of invasive weed species in the northern sector and eutrophication throughout the lagoon. The lagoon is severely threatened by problems like shrinkage of area and decreased depth due to siltation, decreased salinity, macrophyte infestation, eutrophication, and loss of biodiversity. The weak circulation of the lagoon water and poor tidal influx are responsible for the reduction in salinity. These changes in the lagoon environment are a cause of concern for both the local and the national governments, and several conservation measures such as the dredging of a new mouth and public awareness campaigns have been initiated. However, the lack of true catchment basin management has led to the influx of a huge amount of suspended sediment into the lagoon, which has altered its ecology significantly. Siltation, declining salinity, and nutrient inflow have led to extensive macrophyte growth in the lagoon. Free-floating invasive species (e.g., *Azolla*, *Eichhornia*, *Nymphaea*, *Pistia*) and emerging species (e.g., *Ipomea*) have become a common sight. Among the submerged species, *Potamogeton*, *Hydrilla*, and *Najas* are common. Weed infestation increased from 20 km^2 in 1973 to 440 km^2 in 1998 and reached 523 km^2 in 2001. In 2001, emergent weeds covered 86.07 km^2 , free-floating weeds covered 110.74 km^2 , and submerged weeds covered 326.19 km^2 of the lagoon. *Paspalum vaginatum*,

Paspalidium punctatum, *Potamogeton nodosus*, and *Potamogeton pectinatus* dominated the macrophyte community. *Potamogeton* alone accounted for 78% of the invasive species (Ghosh et al., 2006). In spite of the new mouth opening, the weed infestation has not declined, but rather is in the increasing trend possibly due to nutrient enrichment. Thus, the unregulated discharge of various wastes has to be stopped in order to abrogate the weed menace.

The important rivers of this drainage system are the Kansari, the Kusumi, the Janjira, and the Tarimi rivers. The annual total surface freshwater input to the lake is estimated to be 14, 331 million cubic kilometers per year (Panigrahi et al., 2009) which is estimated to carry 1.6 million metric tons of silt into the lake. On the northeast, a channel connects the lake to the Bay of Bengal. A tropical monsoon climate prevails over the drainage basin area of the lake. The lake experiences southwest and northeast monsoons during June to September and November to December, respectively, with average annual rainfall of 1,300 mm (48.77 in.), with 72 rainy days. The maximum air temperature of 39.9°C (103.8°F) and minimum temperature of 14°C (57.2°F) have been recorded. The wind speed varies from 5.3 to 16 m (17 to 52 ft)/s with southerly and southwesterly direction due to the influence of the southwest monsoon and from northerly and northeasterly direction due to the influence of northeast monsoon.

Water quality

The lake is broadly divided into four zones on the basis of water salinity values, namely the southern, central, northern, and outer channels. Tidal influx of seawater during monsoon is arrested by the strong influx of a large amount of freshwater from the northern and central zones. Brackish-water conditions in the southern zone, even during monsoon, prevail due to low water exchange. Salinity in the southern zone decreases during the post-monsoon period and in winter as northern winds facilitate mixing of water with the rest of the lake. During the summer, intrusion of salt water from the outer channel into the lake increases since water level of the lake is at its lowest level. A general increase in salinity of the central and northern zones occurs due to wind-induced mixing by the predominant southern winds, and salinity in the southern zone does not change appreciably. The lake at Daya River mouth behaves like a freshwater lake, and it changes to hyper-saline level of 42 ppt in the outlet channel during the dry period. Lake water is alkaline with pH ranging from 7.1 to 9.6. The southern part of the lake has recorded the highest alkalinity. On a seasonal scale, the DO values show a wide range of variations with average values ranging from 7.2 to 7.9 mg l⁻¹, 8.0 to 8.3 mg l⁻¹, and 6.7 to 7.5 mg l⁻¹ in monsoon, post-monsoon, and summer, respectively. Higher values were reported during post-monsoon followed by the monsoon and summer. The northern and central sectors exhibit lower DO contents as compared to the southern sector (Panigrahi et al.,

2009). High turbidity due to strong mixing of overlying water with sediments results in a low water transparency which ranges from 9 to 155 cm. The huge quantity of silt-borne surface runoff from the catchment area significantly affects the optical property by massive addition of suspended sediments. Phosphate phosphorus (0–0.4 ppm), nitrate nitrogen (10–60 ppm), and silicates (1–8 ppm) are high in the north and northwest part of the lake where most of the rivers discharge into the lake with large amounts of silt and nutrients. The water quality parameters of the whole lagoon before the opening of the new mouth were reported by Nayak et al. (2004); at that time, the nutrient dynamics of the lagoon were heavily influenced by the proliferation of macrophytes. The phytoplankton components revealed by the chlorophyll-a concentration on an average range from 1.95 to 5.75 mg m⁻³, 2.55 to 7.58 mg m⁻³, and 3.79 to 8.33 mg m⁻³, corresponding to post-monsoon, monsoon, and summer, respectively (Panigrahi et al., 2009). Higher values are generally observed in the northern sector except in summer, whereas central sector shows higher concentrations in summer. It is observed that turbidity acts as the key factor controlling the photic property of the lagoon environment (Qasim, 1980; Nixon, 1988; Panigrahi et al., 2009) and thereby controls the phytoplankton production. Ratios of nitrogen to phosphorous in the lagoon suggest that primary production by phytoplankton is nitrogen limited (Panigrahi et al., 2009).

Sedimentation/siltation

The lagoon basin can be considered as shallow, with the highest depth of 2.5 m in the southern sector and some parts of central sector, which was recorded at 3.4 m during 1990 (Tripathy, 1995). The average depth of the lagoon has been decreasing over a period of time. This alarming reduction in the depth of the lagoon is attributed to the deposition of fine sediment particles by the influx from the unmanaged catchment basin and rivers of Mahanadi delta. During monsoon months, the depth of the water column increases due to the massive freshwater influx into the lagoon and minimal flushing of flooded water through the mouth. Thus, the exchange of water and sediment between the lagoon and the sea gets considerably affected by the choking of the outer channel and the northward shift of the inlet mouth (Chandramohan and Nayak, 1994). The shifting and blockage of the lagoon mouth are ascribed to the addition of silt from upstream catchments as well as oceanic longshore transport. The longshore sediment transport (littoral drift) along the coast of the Bay of Bengal is about 0.1 million metric tons (MT) annually, and this shifts the lagoon mouth (the opening to the sea) every year, thereby adversely affecting tidal exchange. The major silt load carried by the tributaries of the Mahanadi River system is 1.5 million MT year⁻¹, while 0.3 million MT year⁻¹ of sediment enters from the western catchment (Ghosh et al., 2006). The upstream erosion and sedimentation processes in the lagoon directly contribute to the loss of lagoon depth as well as the

blockage of the mouth. The total sediment load discharged into the lagoon has been estimated to be 1.8 million MT in 1998 (Patnaik, 1998) and went up to 2.94 million MT in 2001 (Annon, 2003). Spatial variation in sedimentation rate (mm/year) in three zones of the lake, 7.6 in the northern sector, 8.0 in central sector, and 2.8 in the southern sector, has been reported. The sedimentation rate along with the porosity and water content of the sediment cores indicates that the lake has different deposition zones, with comparatively higher sedimentation rate in northern and central sectors and a slow rate in the southern sector.

Distribution of sediment and sedimentary structures

The sediment dispersal patterns and the sedimentary structures in the Chilika are primarily controlled by hydrographic and hydrodynamic conditions prevailing in different areas together with the availability of sediments. In the inlets of the lagoon where current velocity is rather high, sandy sediments predominate, and current ripples, ripple laminations, and medium- to small-scale trough and lenticular cross-beds are pronounced sedimentary structures. By contrast, in areas farther off from the inlets with lower flow velocity, the sediments are silty to muddy. Major part of the lagoon bottom shows an admixture of biogenic debris and mud with occasional intercalated lenses of sand.

Aeolian sand predominates in the sea-facing dunes. The linear barrier bar or spit is chiefly composed of clean sand particularly at its beach faces. The lagoon bottom sediments are parallel laminated and often disturbed by bioturbation structures. Penecontemporaneous deformation structures characterize the layers at greater depths.

Macrobenthic communities play a significant role in producing surface bioturbational structures. Microbial mat layers with curled mud cracks are common in subaerial marginal parts.

Degradation of lake environment and restoration activities

The lagoon was severely threatened by problems like shrinkage of water spread and decrease in depth due to siltation, fall in salinity, macrophyte infestation, eutrophication, and loss of biodiversity when the old mouth was closed due to longshore sediment transport. The weak circulation of lagoon water and poor tidal influx further complicated the conditions leading to deterioration of the environment. Considering the threats faced by the lake, the National Wetlands, Mangroves and Coral Reefs Committee of the Ministry of Environment and Forests, Government of India, and the state government identified the lake as a priority site for conservation and management. Thus, in 1992, the Government of Orissa, concerned by the degradation of the lake's ecosystem and cognizant of significant numbers of people who were dependent upon the lake's resources, set up the Chilika Development Authority (CDA). It was set up for

restoration and overall development of the lake under the Indian Societies Registration Act as a parastatal body under the administrative jurisdiction of the Forest and Environment Department, with the following objective:

- To protect the lake ecosystem with all its genetic diversity
- To formulate the management plan for integrated resource management and wise use of the lake's resources by the community depending on it
- To execute multidimensional and multidisciplinary developmental activities either by itself or through other agencies
- To collaborate with various national and international institutions for the development of the lake

The most effective ameliorative action was the hydrological intervention by opening the new lake mouth and channel to the sea through the barrier beach at Satapada. This improved the spatial and temporal salinity gradients of the lake to maintain the unique characteristics of an estuarine ecosystem. This intervention was undertaken after detailed scientific studies, including three-dimensional mathematical modeling and hydraulics studies on a model prototype, by the Central Water and Power Research Station, Pune and National Institute of Oceanography, Goa. In September 2000, the desiltation of the channel connecting the lake to the sea and opening of a new mouth to restore the natural flows of water and salinity levels were carried out. These actions resulted in a notable increase in the lake's fish yield and a reduction of freshwater weeds. The new mouth reduced the length of the outflow channel by 18 km. Opening of the new mouth provided a favorable increased salinity regime throughout the lake with less fluctuations and improved water clarity. The other restoration activities by CDA involved (1) catchment management in a participatory micro-watershed management in a whole ecosystem approach, (2) protection of bird habitat and of bird species, (3) economic incentives to the local population to stop poaching of birds, (4) measures to improve the socioeconomic conditions, such as training programs to develop ecotourism, (5) provision of solar streetlight systems to island villages, (6) development of a ferry service for isolated villages, and (7) construction of fish landing facilities for fisher folk, as well as educational and environmental awareness activities.

A significant change in water quality was experienced after the opening of the new mouth. The mean seasonal values of different parameters were reported to have shown significant changes in the lagoon environment during the post mouth opening period. The mean depth of the water column of the lagoon during 2001–2003 was lower than that of 1998–2000. This is attributed to better flushing of water and sediment from the lagoon to the sea, as facilitated by the new opening. A remarkable increase in salinity has been noticed during 2001–2003, as compared to before the opening of the new mouth (1998–2000). The

average salinity of the lagoon has undergone a series of visible changes, such as 27–33 ppt in 1957, 13–20 ppt in 1960–1961, 9.4–11.8 ppt in 1961–1964, and 1.38–6.3 ppt during 1995 (Sarkar, 1977; Raman et al., 1990; Siddiqui and Rama Rao, 1995; Panigrahi 2006). The salinity concentration of the lagoon reached 21.5 psu on average, with individual values varying between 0.5 and 31.6 psu during post mouth opening period, 2003 (Panigrahi et al., 2009). The change in salinity had largely occurred due to the exchange of seawater and lagoon water through the newly opened inlet channel. No significant change in pH was observed after the new mouth has been opened. The average total suspended solid (TSS) values of the lagoon during the post mouth opening period remained much below than those seen before the mouth was opened (1998–2000). This indicates a better flushing out of suspended sediments from the lagoon to the sea. The chlorophyll-a concentration lowered in the lagoon; phosphorus nutrients (PO_4^{3-} -P and TP) were enriched and nitrogenous nutrients decreased in concentration following the opening of the new inlet. A significant decrease in freshwater weed proliferation has been reported since the opening of the inlet (Patnaik, 2005). In 2002, Chilika was taken out of the Montreux Record, in light of the improved conditions of the lake. Chilika Lake is the first Ramsar site in Asia to be removed from the Montreux record.

Tourism

Chilika Lake is a popular destination for the ecotourism. The Nalabana Island is the popular bird sanctuary, known as the Chilika Wildlife Sanctuary. Due to a wide range of species of birds, Chilika Lake acts as a popular birding site. It is also quite popular for fishing and angling, and visitors have the opportunity to take the boat cruise around the lake. Visiting the sightseeing destinations around the lake can be an enchanting experience. Thousands of pilgrims flock to visit the Kalijai Island every year to pay homage to the Goddess Kalijai. Satapada where the famous Chilika dolphins are generally seen in a relatively large number serves as the most important tourist spot of the lake.

Conservation and management

- Over a million migratory waterfowl and shorebirds winter here.
- Over 400 vertebrate species have been recorded.
- As an estuarine lagoon, it supports a unique assemblage of marine, brackish, and freshwater species.
- Several rare and endangered species are found in the region.
- The lake supports fisheries that are the lifeline of the community.
- The lake is of great value in preserving genetic diversity.
- There is an increase in weeds and aquaculture activities.

Over the years, the ecosystem of the lake encountered several problems and threats such as:

- Siltation due to littoral drift and sediments from the inland river systems
- Shrinkage of water surface area
- Choking of the inlet channel as well as shifting of the mouth connecting to the sea
- Decrease in salinity and fishery resources
- Proliferation of freshwater invasive species
- An overall loss of biodiversity with decline in productivity adversely affecting the livelihood of the community that depended on it
- Fights between fishermen and non-fishermen communities about fishing rights in the lake and consequent court cases

Conclusion

Anthropogenic activities related to the processes influencing the quality of water of Chilika Lagoon are agricultural drainage, river runoff containing urban sewage, and drainage from the agro-based industries (prawn-processing units). These types of inputs altered the ecology of the lagoon severely and also affected the overall biotic community of the ecosystem. Accumulation of a huge amount of silt gradually decreased the depth of the lagoon and helped the intensification of macrophyte growth. The role of freshwater influx has been critical in bringing salinity changes and cyclic growth and decomposition of macrophytes in the lagoon. A significant improvement in overall quality of the lake environment has been observed after the new mouth opening. However, to restore the ecological stability and economic vitality of the lagoon, an integrated approach to ensure all round development including social, economic, and institutional development is required. The approach to be followed should be catchment area treatment, water management, biodiversity conservation, and sustainable resources development and management.

Introduction

Compared to many lake-rich countries, lakes in China play a less important role compared to other water bodies. In a nationwide water resources assessment project in 1992, Department of Hydrology, Ministry of Water Resource (MWR) of China has concluded that the number of lakes with an area over 1 km² is around 2,300, and the total area of all the lakes amounts to 71,000 km², which is about 0.8% of the total territory of the country. The total storage capacity of all lakes reaches 708 billion cubic meters, which is about 11% of the annual precipitation volume. Besides, there are over 86,000 reservoirs with a total storage capacity of 413 billion cubic meters (Department of Hydrology, MWR China, 1992). Most of the freshwater lakes and reservoirs are exploited and used for multipurpose usage including drinking water, industrial and agricultural production, as well as aquaculture. The assessment also compiled all data from China and divided the nations lakes into five major districts based on their geographical distributions shown in Table 1.

In a more recent investigation carried out jointly by MWR and Nanjing Geographic & Lake Research Institute, a more detailed classification has been implemented and the resulting codes are considered as the national standard for lake classification (MWR and Nanjing Geographic and Lake Research Institute, 1998). The classification report concluded that the total number of lakes (>1 km²) were 2,928 with a total lake area of 93,956 km², much more than that of the 1992 report. The summary of the 1998 report is displayed in Table 2. However, a recent report by Ma et al. (2010) concluded that as many as 243 lakes over 1 km² in size vanished in China during the last 50 years.

Some major lakes in China are described and presented below. The numbers in front of the lake names are marked in the sketch map in Figure 1. The shaded areas (red) in the figure represent other major lakes.

Poyang Lake① (E116°18', N29°05')

Poyang Lake is the largest freshwater lake in China and also the most economically important lake. The area of the lake is 3,960 km² with a storage capacity of 25.9

billion cubic meters. Poyang Lake lies in the grassland, south to Yangtze River and north to Jiangxi Province. Hydraulically, the lake connects to Yangtze River through a neck formed waterway near Duchang. The part south to Duchang is broad and is the main part of the lake. The water area of lake is 161,000 km², receiving flows from the five main rivers in Jiangxi Province, namely, Ganhe River, Fuhe River, Xinhe River, Raohe River, and Xiuhe River. The outlet sluicing water into Yangtze River is at Hukou. The average water volume per annual is about 150 billion cubic meters. Perhaps the most hydrological function of the lake is its regulating volume during flooding season. The regulating capacity of the lake is estimated to take up 20% of the Yangtze River runoff on an annual basis. For instance, in the 1954 flood the lake stored as much as 230 billion cubic meters water, playing a key role in safeguarding the downstream flooding protection.

Dongting Lake② (E112°29', N29°10')

Dongting Lake is the second largest lake of China. It lies in the south bank of Yangtze River and stands in the north part of Hunan Province. The lake extends across Hubei and Hunan with an area of about 2,700–2,800 km², and the storage capacity is 17.8 billion cubic meters. The area of the lake varies significantly due to the water balance and the human impact. There is a tendency of shrinking lake area in recent decades. Besides its intensive fishery and aquaculture-based economy, it has similar hydrological functions as Poyang Lake in retaining flooding water from Yangtze. Extensive human activities in the lake area have made it more vulnerable to environmental changes such as drought and flash flood.

Taihu Lake③ (E120°15', N31°15')

Taihu Lake lies in the bottomland in the south of Yangtze River Delta. It connects closely to the short hills of Tianmu Mountain Chain in the west, and is about 100 km far from the East China Sea. The lake extends across Jiangsu Province and Zhejiang Province but is administrated by Jiangsu Province. Taihu Lake is the third largest freshwater lake in China with an area of 2,292 km² but the water depth is in general less than 2 m. Taihu Lake is one of the most important water supply sources for the surrounding regions including Shanghai. With a population density of nearly 1,000/km² and rapid economic development during recent decades, the water quality deterioration and environmental degradation in the lake area are becoming urgent issues.

Hongze Lake④ (E118°31', N33°23')

Hongze Lake is the fourth largest freshwater lake in China with an area of 1,800 km². It lies in the northwest part of Jiangsu Province and stands in the lower reaches of Huaihe River. The swan-like form of the lake has changed many times in history and expanded in size due to the change of the Yellow River and Huaihe courses.

Chinese Lakes, Table 1 Distribution of lake area and storage in China

Lake district	Lake surface area (km ²)	Percentage to country's lake acreage (%)	Lake storage (10 ⁹ m ³)	Freshwater storage (10 ⁹ m ³)	Percentage to total freshwater storage (%)
Qinghai-Tibet plateau	36,889	51.4	518.2	103.5	45.8
Eastern plains	21,641	30.2	71.1	71.1	31.5
Mongolia-Xinjiang plateau	9,411	13.1	69.7	2.35	1.0

Chaohu Lake⑤ (E117°30', N31°34')

With an area of 753 km² and storage capacity of 1.8 billion cubic meters, Chaohu Lake is traditionally recognized as the fifth largest freshwater lake in China. It is the largest lake in Anhui and lies in the middle of the Province. The lake shape looks like a water caltrop. The total population of the area is about five million and they are facing similar water quality and environmental degradation problems as Taihu.

Dianchi Lake⑥ (E102°38', N24°45')

Dianchi Lake is a freshwater lake located in the southwest of Kunming city, Yunnan Province, a few kilometers away

from the city center. In ancient times, the lake was called Diannanze, also called Kunming Lake. The historical book *Post Han Dynasty and Southwest Minorities* recorded: "This city has a lake that extends around 200–300 miles. The headstream is sufficient and water is like in backward flow." This description gave the name of the lake. It is a geologically fault formed lake at the height of 1,886 m above sea level. The lake used to be among the top five in size in China but has shrunk to below 300 km² in recent decades. Together with Taihu, Dianchi is considered as the most ecologically degraded water body characterized by algae blooming and general eutrophication.

Chinese Lakes, Figure 1 Location of major Chinese lakes; the numbers on the map refer to the respective numbers in the text.

Erhai Lake⑦ (E100°11', N25°47')

Erhai Lake was called Yeyuze or Kunmingchi Lake in ancient times. It is located in Dali Bai Autonomous Prefecture in west Yunnan Province. The length from north to south is about 40 km and the average width from east to west is 5–6 km. The average water depth is 12 m and the deepest place is about 23 m, in the east of the lake. The area of the lake is 246 km and the storage capacity is 2.95 billion cubic meters.

Jingbo Lake⑧ (E128°56', N43°52')

With the original name of Meituohu Lake, Huhanhai Lake, and Bi'erteng Lake, Jingbo Lake is located in Ning'an County, Heilongjiang Province, and in the upper reaches of Mudanjiang River. The length from north to south is 45 km and the widest distance between east and west is only 6 km. The lake area is about 95 km² with a storage capacity of 1.63 billion cubic meters. The south part of lake is shallow and the north is deep with a maximum depth down to 62 m. The formation of this lake is identified to be caused by ancient volcanic eruptions.

Wudalianchi Lake⑨ (E126°06', N48°18')

Wudalianchi Lake is located in the upper reaches of Baihe River, which is the tributary of Mohe River, 23 km from Dedou County. The lake is the northernmost lake for China.

It has been recorded in history books that, in the year 1719, two volcanos named Laohei Mountain and Huoshao Mountain in this area erupted, the magma jammed Baihe River and formed the present Wudalianchi Lake. Today, the lake area is a popular tourist attraction and it is also listed on the UNESCO's World Geological Park.

West Lake⑩ (E120°08', N30°15')

There are several lakes in China with this name. The best known one is the beautiful one located in the west of Hangzhou City. The total area is about 5.6 km with an average water depth of 1.5 m. The lake is divided into five parts, namely, Outer Lake, Beili Lake, Yue Lake, Xili Lake, and Xiaonan Lake. In ancient times, there was once a shallow bay here, evolving into a lake little by little. In the three directions of the lake stand hills. The Baidi Bank and Sudi Bank lie in the lake, forming two chains. There are three small islands in the central part of the lake. The lake is the best known lake in China by the public thanks to its scenery surroundings around the lake with many ancient inscriptions, structures, and stone sculptures. The lake area is also listed on the UNESCO's World Heritage Catalogue.

Qinghai Lake⑪ (E100°11', N32°58')

With the original name of Xihai, Qinghai Lake is located in northeast Qinghai Province. Hydrologically, it belongs

to the Chaidamu Inland Basin. This saline lake is considered as the largest lake in China (about 4,300 km²). In Mongolian, it is called “Kukunuoer” and in Tibetan with the name “Cuowenbu,” and they all means a “blue lake.” The lake is surrounded by mountains. In the north and east, there lie Datong Mountain, Tongbu Mountain, and Riyue Mountain of the Qilian Mountain range, the height of which is between 4,000 and 5,000 m; in the south and southwest, there stands Qinghainan Mountain, with the height over 4,000 m. The Qinghai Lake Basin is in the center, the lowest part of the lake area. The lake area is rich in fishery and migration birds, many of the species are on the national protection lists.

Zhaling Lake and Erling Lake^⑫ (E97°14', N34°54' and E97°43', N34°50')

Zhaling Lake (550 km²) and Erling Lake (600 km²) are located in Maduo County in Guoluo Tibetan Autonomous Prefecture and Qumalai County which belongs to Yushu Tibetan Autonomous Prefecture in Qinghai Province. Zhaling Lake is in the west and Erling Lake is in the east. Hydrologically these two sister lakes belong to the Yellow River Basin. The local Tibetan people, who have lived in the lake area with a long history, call Zhaling Lake “Cuojialang,” meaning the white long lake; and Erling Lake for “Cuolelang,” meaning the blue long lake.

Namucuo Lake^⑬ (E90°35', N30°40')

Namucuo Lake is located in west part of Tibet but is classified as in Northern Tibetan Basin. It is the grand lake (1,960 km²) with the greatest height in the world. In Mongolian, it is named “Tenggeliha,” meaning “the lake in the sky.” The shape of the lake is like an oblong. The length from east to west is 70 km and the width from north to south is 30 km. The lake has a storage capacity of 76.8 billion cubic meters. In the south of the lake stands the grand Nianqingtanggula Mountain and in the north and the northwest are small hills. There are three islands on the lake. In the southeast, a peninsula stretches into the lake. The peninsula is formed by limestone and the characters of karst topography are predominant.

Yangzhuoyongcuo Lake^⑭ (E90°43', N28°58')

Yangzhuoyongcuo Lake is also called Baidi Lake and in Tibetan it is named “Yumucuo,” meaning “the lake of swan.” The shape of the lake is like the claw of hen. The bank of the lake twists greatly. In the areas of Zhamalong and Baidi in the north part, there is the narrowest part of the lake with an extent of only 1–2 km. The rest three sides of the lake are wide and the extent is 3–8 km. The lake line is 250 km long. The height of the lake is 4,441 m (above mean sea level) with an area of 638 km². The depth of the water is 30–40 m, and the deepest place is 59 m. It is the largest inland lake in Southern Tibetan Basin with a storage capacity of 16 billion cubic meters. Besides, there are a number of small lakes around Yangzhuoyongcuo, such as Kongmucuo, Chencuo, and Bajiucuo. Some of

them connect directly with Yangzhuoyongcuo, and some only connect the lake during the wet period. In this way, the lakes form the Yangzhuoyongcuo lake chain.

Hulun and Beier Lakes^⑮ (E117°23', N48°57' and E117°44', N47°50')

Hulun Lake is also called Dapen Lake. Geographically it is located in the northeast Chinese border area, on the grassland among Xinbaerzuoqi, Xinbaeryouqi, and Manzhouli City in the Inner Mongolia Autonomous Region, but hydrologically classified to belong to Heilongjiang River Basin. It is 80 km long and 35 km wide, with a perimeter of 375 km. The lake area is about 2,300 km² and the storage capacity is up to 11 billion cubic meters. The deepest place is 8 m. It is one of the biggest lakes in the Inner Mongolia Autonomous Region. Together with the Beier Lake, which is much smaller (600 km²), located on the south of the grassland and the Sino-Mongolian frontier, the two lakes are also called sister lakes.

Daihai Lake^⑯ (E112°40', N40°37')

Daihai Lake is located in Liangcheng County in the Inner Mongolia Autonomous Region. It is a rift valley-shaped lake surrounded by mountains. The lake basin lies in the southeast of the basin. It is roughly 20 km long and 10 km wide. The area of the lake is about 133 km² and the storage capacity is 1.33 billion cubic meters. The deepest place is 18.4 m. The mineralization of the lake water is as high as 2.5 g/L and it is classified as inland saltwater lake since there is no outlet.

Luobupo Lake^⑰ (E90°38', N40°20')

Luobupo Lake (Lop Nur) is located in the east of Talimu (Tarim) Basin in Xinjiang, which is China's largest inland basin. In ancient times, it was called Zeyan Lake or Puchang Sea. In Mongolian, it is known as Luobuluoer, which means the lake converging many rivers. Unfortunately, this oasis in the Gobi desert gradually dried up and disappeared during 1950s due to desert expansion and human activities. According to historical books, this ear-like lake had area of over 5,000 km² and was a famous inland lake in Chinese history with the finding of some archeological facts such as the ancient kingdom of Loulan.

Chakayanchi Lake^⑱ (E99°06', N36°42')

Chakayanchi Lake is located in northeast corner of Qaidam Basin in Qinghai Province. In the north, it is near Kukuluorling Mountain of Qilian Mountain Range, and in the south it is close to Wangduoxiu Mountain. The lake shape is like an ellipse. It is 14.8 km long and 9 km wide, with an area of around 105 km². The area around the lake is one of the China's famous lake-salt producers.

Bositeng Lake^⑲ (E87°03', N41°58')

Located in the middle of the Xinjiang Uygur Autonomous Region, Bositeng Lake is also called Bakaci Lake. The

first description of this lake can be found in Chinese history books in Han Dynasty and Northern Wei. With a lake area of nearly 1,000 km², it is considered as the largest lake in Xinjiang and one of the largest inland freshwater lakes in China.

CIRCULATION PROCESSES IN LAKES

Lars Bengtsson

Department of Water Resources Engineering, Lund University, Lund, Sweden

Introduction

The dynamic processes in a lake are governed by forces exerted on the water body and forces acting within the water mass. The direct circulation generating mechanisms are the wind, which transfers momentum and energy to the water surface, river through-flow, and atmospheric heat exchange and also heat exchange between water and sediment, which gives rise to density currents. In oceans and large enclosed seas different atmospheric pressure changes over the water surface force large water masses to move, which means that this is relevant also for the Caspian Sea. Tides are very minor even in the biggest lakes. The wind generates currents directly when momentum is transferred to the water surface. When the wind has ceased to blow there are slow back-forth water movements called seiches. All currents are modified by the bottom configuration and the density stratification. The currents are influenced by the rotation of the Earth. On the northern Hemisphere there is a tendency for an inflowing river to follow the right-hand side of the lake. The different circulation phenomena are described below.

Wind-induced circulation

When the wind is acting on a lake surface, momentum is transferred to the water. The water surface is set up slightly in the wind direction. The setup depends on the wind speed and water depth, as described below; the slope of the surface is very minor of the order 10⁻⁶, i.e., mm/km. There is a force balance between the wind shear (and partly also the bottom shear from the bottom current) and the gravitational forces against the wind due to the

tilting of the water surface. In a homothermal lake, which is neither extremely shallow nor deep, the velocity profile is as shown in Figure 1. The surface velocity is as a rule of thumb 2% of the wind velocity. In very shallow lakes of depth about 1 m, the currents along the shores are most often in the wind direction, while the return current is in the middle of the lake. Even in lakes as small as 10 km² and depth of 10 m, the circulation is influenced by the Earth's rotation. The surface current tends to turn to the right related to the wind direction.

The slope of the water surface can be determined by balancing the wind force, τ , and the gravitational force from the tilting. Neglecting the bottom shear, mainly because its direction is not obvious, the gradient, I , of the water surface is

$$I = \frac{\tau}{(\varphi g h)}$$

where φ is density of water, g is the acceleration of gravity, and h is the water depth. The shear force from the wind is related to the wind speed as

$$\tau = \varphi_a C_d W^2$$

with W as wind speed and C_d as a drag coefficient, which is about $1.0 \cdot 10^{-3}$ or slightly higher and to some extent depends on the stratification of the air. The atmospheric density is φ_a .

As an example consider the situation when a 7 m/s wind blows over a 3-km-long and 6-m-deep lake. The surface current will be about 14 cm/s, the wind shear about 0.06 N/m², and the slope of the water surface $1.0 \cdot 10^{-6}$, which means that the water level difference between the down- and upwind parts of the lake is only 3 mm.

Mathematical models of wind-induced circulation in complex lake basins have been in use since more than 35 years. The wind shear and its distribution over the lake surface are required as input and also the bottom topography of the lake and the stratification of the water (unless the model is run over a very long time and the temperature development is included in the model). Equations for determining the vertical mixing of momentum must be part of the model or a priori values of the vertical eddy viscosity and its distribution must be used. Correct estimation of the vertical eddy viscosity is crucial for good modeling results.

Seiche currents

Already in the 15th century periodic oscillations of the water surface were observed on Lac Lemman (Lake Geneva). The periodic movement was named seiche. The character of the seiche is determined by the geometry of the lake and by the water stratification. The oscillations may be free, as when the wind ceases to blow, or forced by rhythmic changes of the wind or by other external forces.

A surface seiche has a short period (minutes or hours) and small amplitude (mm or cm). The theoretical

Circulation Processes in Lakes, Figure 1 Wind-induced velocity profile in an elongated homothermal lake of depth of about 4–8 m when the wind speed is about 7 m/s.

period, T , in an elongated lake of length L and mean depth h with homothermal water is

$$T = 2 \frac{L}{\sqrt{gh}}$$

Since the amplitude is minor, the currents when water masses are moving back-forth are also minor. However, in very shallow lakes the seiche currents can be significant. The mean current, u , in the middle of a lake is

$$u = 2A \frac{\sqrt{g/h}}{\pi}$$

with A as the amplitude of the seiche, i.e., half the maximum difference of the water level at the two end shores. In the Hungarian Lake Balaton, which is 80 km long and has a mean depth of less than 3 m, a 7 m/s wind should cause the water surface to tilt $2 \cdot 10^{-6}$, which is an amplitude of 0.08 m. The mean seiche current is then about 10 cm/s. Wind speeds of 20–25 m/s ought to give rise to back-forth currents greater than 1 m/s, which also has been observed.

During summer it is very common that a lake is stratified with warm rather homothermal water, epilimnion, above colder denser water, hypolimnion. The temperature drop is within the metalimnion over a few meters. When the metalimnion is rather thin this layer or border between the epilimnion and hypolimnion is called the thermocline. When there is a setup of the water surface, also the thermocline must tilt, but in different direction than that of the surface and with a much stronger slope. If the thermocline is very sharp and the stream velocities are low, the slope of the thermocline should be related to that of the water surface as

$$I_{\text{thermo}} = -I_{\text{surface}} \frac{\varphi}{\Delta\varphi}$$

$\Delta\varphi$ being the density difference between the hypolimnion water and the epilimnion water.

Also the thermocline may oscillate, but with a large amplitude and with a long period (hour, days). Since the amplitude of the internal seiche is large, large water masses are set in motion. If the thermocline is close to the bottom, the generated currents can be quite large. It may be that the thermocline is forced to tilt so much that it reaches the water surface near one end of the lake. This means that bottom water reaches the surface. This phenomenon is called upwelling.

Through-flow

A river entering a lake generates water movements, but since the lake is deeper and wider than a river, the currents are generally minor and observed only near the river inlet. Because of the Earth's rotation there is a small tendency that the river initially follows the right-hand side of the lake. More important is the effect of the different density of the river water and the lake water. After initial mixing the river water may be layered within certain depths.

Density currents

Horizontal density differences or anomalies within the lake water always generate currents. Nature strives to obtain density-stable conditions. Horizontal density gradients tend to be established when the water is heated differently (differential heating) over the lake. It may be that more solar radiation is received per unit volume in shallow parts such as bays as compared to deep parts of a lake,

Circulation Processes in Lakes, Figure 2 Differential heating causing convective circulation and water exchange between warmer bay water and the colder lake proper.

Circulation Processes in Lakes, Figure 3 Differential heating due to shading by vegetation resulting in warmer water in the lake proper and movement of surface water into the vegetated area and corresponding outflow of water near the bottom.

Figure 2, or it may be that some parts of the lake are shaded and less exposed to solar radiation than other parts, Figure 3. Horizontal temperature gradients may also be caused by patches of high turbidity, which absorb more of the heat closer to the surface than clear water does. In the winter, heat released from the sediments generates slow density currents; see the article “*Ice Covered Lakes*”.

Currents induced by differential heating may reach up to 10 cm/s, but are more commonly only a few cm/s or even less. When the differential heating is due to shading, these convective currents tend to be in a different direction during daytime and nighttime. When the heat flux is from the sediments the velocities are very small and not measurable, but are continuous for most of the ice covered period.

As a quantifying example of differential heating, in a study of Lake Velen in Sweden it was found that in early June the water temperature in a shallow bay, 2.5 m deep, tended in the course of the day to become 1°C warmer by late afternoon than the surface water in the lake proper and then during the night return to the same temperature as the water outside the bay. The current, c , induced by the temperature gradient is sometimes crudely estimated from the sluice-gate (lock) equation:

$$c = 0.5 \sqrt{g^I h}$$

where g^I is the densimetric gravity $\Delta\phi/\phi g$. In the above given example the convective surface current out of the bay into the main part of the lake would be 3 cm/s.

Circulation Processes in Lakes, Figure 4 Temperature difference between open water and reed-covered area in Lake Kranke, Sweden, and surface velocity generated by the differential heating. The surface currents are into the reeds during daytime and out of the reeds during nighttime.

When parts of the lake surface is shaded, it tends during sunny days not to be heated as much as where there is open water. During daytime a circulation pattern as the one shown in [Figure 3](#) develops. During nighttime the open water cools faster and the circulation is reversed. An example from Lake Kranke in southern Sweden is shown in [Figure 4](#). The temperature difference reaches 0.3°C and the surface current about 1 cm/s.

Circulation in ice covered lake induced by heat flux from the sediments is discussed in the article on ice covered lakes. These currents are of the order m/day.

CLASSIFICATION OF LAKES FROM HYDROLOGICAL FUNCTION

Lars Bengtsson
 Department of Water Resources Engineering, Lund
 University, Lund, Sweden

Definition

Lakes can be classified in different ways, according to their *geological* origin (see [Classification of Lakes from Origin Processes](#)), according to their *trophic* state (see [Trophic Lake Classification](#)), which is according to the biological status, according to the *thermal regime* (see [Thermal Regime of Lakes](#) and [Stratification in Lakes](#)), which is related to the climate, or according to the hydrological conditions relating to the character of the in- and outflows. In this entry, lakes are classified according to their *hydrological function* (see also [Water Balance of Lakes](#)).

Classification of Lakes from Hydrological Function,
Table 1 Hydrological classification of lakes

Inflow	Outflow	Lake type	Settings
Surface	None	Terminal	Large lakes
Surface	Surface	Spillover	Most common lakes
Groundwater	Surface	Spillover	Downstream sand formation
Groundwater	Groundwater	Closed pond	Groundwater system

The hydrology of a lake is determined by the water inflows and outflows including precipitation on and evaporation from the lake surface and, thus, by the climate and the geological settings. Some lakes have no outflow. These lakes are *terminal lakes* or *closed lakes* often referred to as *endorheic lakes*. Evaporation from the lake is considerably larger than the precipitation on the lake. The lake area is large relative the full river basin area. The lake level varies much and thus also the lake surface area. The water is usually salt. The lakes are often very big such as the Caspian Sea, Lake Chad and very sensitive to climate variations and human impact, the Dead Sea and the Aral Sea. If the climate becomes more humid such a lake may turn into a spillover lake, or such a lake may have been a lake with spillover in a previous climate.

Most lakes have outflows. The lake level does not vary very much, since increased water level means increased outflow. These *spillover lakes* or *overflowing lakes* may have one or several *surface inflows* and also groundwater inflows. Groundwater inflows are usually minor if there are inflowing streams. Groundwater inflows dominate if the lake is the outlet of a *spring* or if the lake is situated within or downstream a *sand formation*.

Some lakes or ponds are merely a part of the *groundwater system*, with the inflow as well as the outflow being groundwater flow. Glaciated hollows filled with groundwater may be such lakes, but such kettle lakes may also have some surficial inflows or outflows.

The classification is shown in Table 1.

The classification can be driven further by considering the inflow variations of the annual cycle of precipitation, evaporation from the lake and the inflow.

CLASSIFICATION OF LAKES FROM ORIGIN PROCESSES

Lars Bengtsson
 Department of Water Resources Engineering, Lund
 University, Lund, Sweden

Introduction

There are 100 million lakes in the world larger than 0.01 km². Lakes can be classified in different ways, according to their *geological* origin, to their *trophic* state (see *Trophic Lake Classification* in the Encyclopedia),

which is according to the biological status, according to the *thermal regime* (see *Thermal Regime of Lakes* and *Stratification in Lakes*), which is related to the climate, or according to the *hydrological conditions* relating to the character of the in- and outflows (see *Water Balance of Lakes* and *Hydrological Classification of Lakes*). In this entry, lakes are classified according to their geological origin. A lake is formed when water fills a depression. A depression can have been formed in different ways. Lakes are mainly created as consequences of *tectonic*, *glacial*, or *fluvial processes* but there might also be other processes involved. Tectonic lakes are deep. Glacial lakes are found where there has been land ice. The glacial lakes are rather shallow and this type of lakes is often found clustered within a region. The fluvial lakes are less common. They are very shallow.

Glacial lakes

There are a large number of glacial lakes in Northern America, Scandinavia, and Russia. These lakes were created due to the glaciation during the Pleistocene. Depressions were formed by glacial features as moraines and glacial scour. The climate is such that precipitation dominates evaporation and thus favors the existence of lakes. The glacial lakes constitute almost 50% (1,250,000 km²) of the surface area of all lakes. The lakes are formed either in direct contact with the ice, behind depositions from glaciation, or depressions eroded during prior glaciation. The Great Lakes of North America are glacial lakes but most of the glacial lakes are quite small and instead abundant in certain regions such as in the Finnish Lake District. Some glacially formed lakes may be deep. Lakes that are formed in long glacially formed valleys are fjord lakes. If they are directly attached to the sea, as there are so many examples of in Norway, they are ordinary fjords. Examples of deep glacial lakes can be found in the Scandinavian mountains. The deep lakes in Switzerland and northern Italy may also be classified as fjord lakes.

Tectonic lakes

Tectonic lakes are created from the movement of the Earth's crust. The deepest and oldest lakes in the world have evolved from tectonic processes. The Caspian Sea is the biggest one with an area of about 370,000 km² (varying rather much since the Caspian Sea is a terminal lake), which is 15% of the world's lake area. The Caspian lake volume is 45% of that in all lakes. The other tectonic lakes when not including the Caspian Sea make up about 20% (525,000 km²) of the surface area of all lakes but since they are very deep 32% of the total volume of all lakes (76% including the Caspian Sea). The Caspian Sea and also the Black Sea were formed during the convergence of Africa and Arabia with Eurasia, when also the Mediterranean sea was formed. In Late Tertiary the Black sea was a terminal lake as the Caspian Sea is today. The extremely deep lakes, Lake Baikal and Lake Tanganyika, were formed during the early phases of continental rifting. There are also shallow tectonic lakes. Lake Chad is such

an example and Lake Okeechobee. Lake Chad is in a dry environment. It is formed in a low interior region of Africa due to subsidence. Lake Okeechobee was formed from the uplift of the ocean floor.

Fluvial lakes

Fluvial lakes are very shallow. Although they constitute almost 10% of all lake surface area, they hold only about 0.3% of the volume. Sediments transported by rivers may accumulate, for example, in river bends, and create a form of dam, or running water may excavate depressions. Meandering rivers may take a new course through a river bend and then a lake, oxbow lake, may be created. A river system with an oxbow lake often includes many such small lakes. Fluvial lakes may also be created near the coast, when longshore coastal currents deposit sediments that block river outflows. The fluvial lakes can be created due to processes acting over a longtime, or as a consequence of very extreme events.

Lakes formed by other processes

Some lakes have origin different from the three major ones. Lakes may be formed by volcanic activity, by solution in karst terrains, meteorites, and landslides or formed by the wind.

Volcanic lakes formed from volcanic activity can be found in Iceland, Italy, and New Zealand. In karst terrain there is solution of subsurface rocks by groundwater leading to formation of hollows which can be filled with water forming usually small *karst lakes*. This kind of lakes is common on the Balkan Peninsula.

Landslides may dam water in mountainous terrain. Lakes created in this catastrophic way may be temporary and can be drained again almost in a catastrophic way. Damming of rivers may also be due to *accumulation of plant material*. Mammals, especially the beaver may build dams so that a lake is formed upstream.

Lakes (*wind formed lakes*) can be formed by wind action. Sediments transported or eroded by the wind may form irregularities in the terrain. Windblown sand may block rivers. These lakes are shallow.

In large regions of the Northern Hemisphere the land is still rising. The sill between some shallow bays or fjords and the sea is slowly coming above the sea level cutting of the bays from the sea, and the bays and fjords turn into fresh water lakes sometimes called cutoff lakes. There are numerous such examples along the Baltic in the north of Sweden and Finland.

Of course, the very large dams are built by man. *Man-made lakes* or *reservoirs* are a very special form of lakes. They are found almost all over the world. They are described in several entries in the encyclopedia.

CLIMATE CHANGE EFFECTS ON LAKES

Thorsten Blenckner

Baltic Nest Institute, Stockholm Resilience Centre,
Stockholm University, Stockholm, Sweden

Introduction

The global environmental changes that are apparent today are mainly anthropogenic due to the growing human population and its high activity of resource consumption. The most obvious trends concerning ecosystem impacts are the anthropogenic changes in biological diversity and alterations in the structure and functioning of the food web. Climate change is one of the most important factors within the global change issues, and therefore, the impact of climate on ecosystems has been widely tested using historical data, experiments, and model simulations.

In temperate aquatic ecosystems, most of the ecologically important characteristics are influenced by climate change such as changes in temperature, evapotranspiration, frequency and magnitude of precipitation, wind, storm, and fire events, length of the ice-free season, and the depth of the mixed layer. In general, many water quality problems may worsen by climatic change, particularly those relating to eutrophication, such as bottom-oxygen depletion. However, an extreme uncertainty exists at any case-specific level, which is related often to specific characteristics of lakes (e.g., depth, retention time) and/or catchments, such as land use patterns.

In the following, four physical responses will be discussed followed by presenting an overview of ecosystem-wide changes and the potential effects of no direct-related drivers.

Ice cover

The timing of ice freeze and breakup, one of the longest and widespread limnological variables, has been used often as an indicator for regional climate change. Duration

of ice cover is driven by several meteorological variables, of which air temperature has been shown to be the most important one.

A long-term trend toward shorter periods of ice cover due to a later freezing and an earlier ice breakup has been reported for lakes around the northern hemisphere. The trend of an earlier ice-out increases the ice-free period and raises lake temperatures in spring in many reported studies from global distributed lakes. In Northern Europe, the duration of the ice cover period and the timing of freeze and breakup greatly affect lake systems, in particular, the succession events in plankton and partly underwater plant dynamics.

Water temperature

Surface water temperatures often show a strong coherent increase following the warming of air temperature across European lakes. A faster temperature rise in the spring (due to earlier ice-out dates) preceded the beginning of spring stratification, which may influence nutrient cycling and phytoplankton dynamics. Consequently, effects of higher water temperatures on the lake mixing regime could lead to dimictic lakes (fully mixed twice a year) turning into warm monomictic lakes.

Overall, temperature affects all physiological processes, thereby influencing the growth of organisms. The magnitude in which physiological rates change with respect to temperature is generally in good agreement with an Arrhenius formulation. For example, zooplankton found in lakes can tolerate fairly high summer temperatures, but small increases in the winter temperature, in some lakes significantly related to the timing of ice breakup, can strongly affect the overwintering and seasonal dynamics of zooplankton species such as *Daphnia* and *Eudiaptomus* through a strong temperature-dependent growth rate.

The survival and growth of fish species, for example, depends often on temperature. Thermal limits of some fish species, altered by global warming, can induce changes in spatial distribution. Temperature-induced changes in the growth rate of predatory fish may result in cascading effects through the entire food web.

Stratification

Most temperate deep lakes are stratified during summer, with a warm surface water (epilimnion) and cold deep water (hypolimnion). The most crucial triggering factors for the timing of phytoplankton blooms are light and turbulence, which are both influenced by stratification and therefore directly affected by climatic variation and change. Consequently, strong relationships between the timing and the winter climate were found in European lakes. Differences in the individual lake response depend often on the morphometry of the lake. For example, in Lake Constance (Germany) – a large and deep lake which generally is not covered by ice in winter – the spring bloom only occurs under stratified conditions, because reduced mixing increases light availability for phytoplankton. Generally, an enlarged mixing depth increases

the proportion of incoming light, which is attenuated abiotically within the mixed layer. This leads to a decrease in phytoplankton production averaged over the mixed layer with increasing mixing depth. By contrast, in shallow lakes with a lower mixing depth, the phytoplankton spring bloom is often associated with ice cover disappearance (determined by winter climate), influencing the light availability as observed for example in Lake Müggelsee, Germany, and Lake Erken, Sweden. Later in the year, conditions in the lake appear to be more complex and stratification becomes the predominant triggering factor. For example, longer periods of stratification can promote a dominance of potentially toxic cyanobacteria as higher water temperatures prolong the stratification period and create favorable conditions for cyanobacteria. Additionally, large cyanobacteria colonies (besides other phytoplankton groups) are resistant to grazing by zooplankton, especially in eutrophic lakes. These two mechanisms partly promote the dominance of cyanobacteria in stratified lakes at a warmer temperature regime. Longer periods of summer stratification and higher hypolimnetic temperature are also projected to cause increased hypolimnetic anoxia, or at least lower oxygen concentrations. This condition often leads to an enhanced phosphorus release from the sediment, in particular, important as phosphorus is the main limiting factor in lakes.

Hydrology

The inflowing water from streams and rivers and their loading depends very strongly on precipitation and land use, e.g., the intensity of agriculture. The amount of the inflowing water further affects the hydrological water residence time in the lake which further influences how long for example phosphorus molecules are recycled within a lake. Stratified lakes with a water residence time longer than 1 year have a higher potential to suffer from an amplified climate-related eutrophication as the warmer climate may intensify the stratification and thereby cause a P released from P-rich sediments. In contrast, in lakes with short residence time (months), the phosphorus released from the sediment is flushed out relatively quickly and therefore cannot contribute to next-year phytoplankton development. Decreases in water residence time, for example, through an increase in precipitation with an associated higher runoff, can decrease concentrations of nutrients, as water residence time scales the rate of the ecosystem response to chemical inputs and to climate change and variability. The water level of closed lakes where the hydraulic load is counterbalanced by evaporation and rather stable seepage serves as one of the best indicators of long-term climatic variation.

Ecosystem changes

Climatic changes relevant at a species level are likely to vary at the ecosystem scale among lakes. Weak links in food web interactions, in particular, dampen oscillations between consumers and resources. This implies that not all responses at a specific trophic level are propagated

to lower trophic levels or have significant impacts on ecosystem processes. Additionally, a prolongation of the climate signal due to food web interactions is possible as the signal of, for example, winter climate can be detected in the clear water phase in early summer (induced by high zooplankton grazing) or in summer phytoplankton composition and biomass. A system approach is necessary to examine the cascading effects in response to climatic change and variability. The magnitude of a climate-driven response of an autotrophic organism does not necessarily have to be mediated or cascaded to the heterotroph species, or vice versa. Another example indicates that a consecutive period of five mild winters led to a complete change of the spring phytoplankton bloom, from a dominance of diatoms and cryptophytes to a dominance of cyanobacteria in a German lake. This illustrates, furthermore, that the response of phytoplankton, and probably also other lake biota, to climatic variation might be totally different from the response of a warming trend, as many ecosystem processes are nonlinear. Furthermore, the nonlinearity in the response to environmental variables of animals and plant may cause progressive changes to be interrupted by drastic switches to a contrasting ecosystem state. One such example is the shift between the clear water (macrophyte dominated) and the turbid (plankton dominated) state of shallow lakes. A recent study in a Swedish lake showed that climate variability alone cannot explain such a shift, but is likely to amplify this to a multi-causal stress and, therefore, reduces the resilience of the clear-water state in shallow lakes.

Impacts of other anthropogenic drivers

In the past 40–50 years, many lakes, particularly in Europe and the USA, have been subjected to an anthropogenically caused increase in the supply of nutrients and other substances, e.g., organic pollutants. This supply decreased partly in the late 1980s or early 1990s. While improvements in wastewater treatment over the last decades have reduced inputs of nutrients from point sources, the increase in nutrients from diffuse sources is still a major problem and, for many lakes, remains the predominant concern. Additionally, catchment alteration, acidification, dam regulation, agriculture, and the waterborne sanitation solution can complicate a separation of the various influences on ecosystems. Therefore, to clearly disentangle the effects of climate on important lake processes from anthropogenic nutrient effects are very difficult. The effects of multi-stressors on ecosystems is very complex in particular, as the stochastic interplay of these effects and the nonlinear or time-lagged response of the food web are very difficult to foresee.

CLIMATE CHANGE: FACTORS CAUSING VARIATION OR CHANGE IN THE CLIMATE

Cintia Bertacchi Uvo

Department of Water Resources Engineering, Lund University, Lund, Sweden

Introduction

Climate changes are variations that happen in the climate on a certain location or globally and on different time perspectives. On a geological time perspective, the climate of the Earth has changed drastically in the past. It has experienced long periods (thousands of years) of very high or very low temperature if compared to the temperature experienced today ([Figure 1](#)). After the latest ice age (about 13,000 years ago), the variations in climate have been milder if compared to the previous ones. Changes in the past climate in a geological perspective, also known as paleoclimate, can be inferred through traces left on glaciers or on ice sheets, tree rings, lake beds, caves, among others.

Causes and consequences

The causes for changes in climate can be many, and the consequences of each of them can last for longer or shorter time periods. On a *geological* perspective, the drift of the continents have caused changes on the global climate that follows a geological time scale, that is, hundreds of thousands of years. On the other hand, *volcano* outbreaks that are also related to the continents' drift can change the climate on a shorter time scale by throwing ashes into the atmosphere. The ashes shade the solar radiation by increasing the albedo of the upper atmosphere and cool down the atmosphere below. Climate changes caused by volcano outbreaks can last from a few days to a few years depending on the intensity of the outbreak, the amount of ashes liberated, and the altitude reached by the ashes. An example of the consequences of volcano outbreak is the year 1816, known as the “year without a summer.” From late spring to early fall that year, temperatures were abnormally low mostly in the Northern

Climate Change: Factors Causing Variation or Change in the Climate, Figure 1 Temperature difference between today's global average temperature and past global temperature for the latest 450,000 years as estimated by the Vostok ice core, Antarctica (Petit et al., 1999).

Climate Change: Factors Causing Variation or Change in the Climate, Figure 2 Example of variation of Earth's orbit around the Sun.

Hemisphere due to the ashes thrown into the atmosphere by the eruption of the Mount Tambora volcano on the island of Sumbawa, Indonesia, on April 10 and 11, 1815 (Stothers, 1984).

Solar radiation

The *solar radiation* is an important factor determining the climate. The amount of radiation that reaches the Earth and how it is distributed over it are key factors for the definition of the climate in such way that changes in solar radiation amount and distribution cause changes in the climate. Changes in solar radiation amount and distribution can be caused by changes on the inclination of the Earth's axis in relation to the Sun, which affects the distribution of the sun radiation, or by changes on the Earth's orbit around the Sun that affects the intensity of the solar radiation received by the Earth. Such changes cause climate changes on a very long time perspective (hundreds of thousands of years). An example of such variation on the Earth's orbit can be seen on Figure 2.

In addition to that, the solar activity also varies and with it the intensity of the solar energy that reaches the Earth. A cycle of about 11 years in the sun activity is well known, and that impacts the Earth climate, creating a cyclic change on the climate. The cyclic solar activity can be seen in the number of sunspots observed per year as represented in Figure 3.

Cyclic climate changes on a relative short time perspective are called climate variability. Several other natural

phenomena can impact the climate causing changes or variability in climate. Many of these phenomena are related to the circulation of the oceans or of the atmosphere, or of both ocean and atmosphere. The Gulf Stream and the El Niño–Southern Oscillation (ENSO) are among the best known of such phenomena.

ENSO

ENSO is a climate phenomena caused by the interaction between the Pacific Ocean and the atmosphere. It presents an oscillation of 2–4 years and impacts the climate all around the world. The ENSO oscillation can be seen at the temperature of the surface of the Central Pacific Ocean. Figure 4 shows the difference between the sea surface temperature and the average sea surface temperature on Central Pacific. Periods when the sea surface temperature is above normal (red color) are named El Niño events and below normal (blue color) are named La Niña.

ENSO events change the climate of the Earth regionally and seasonally so that some regions become warmer than normal or colder than normal, or drier or wetter as exemplified in Figure 5 for the winter in the Northern Hemisphere (December–February).

Human activities

Human activities can also cause climate change that can be on a small area or globally. For instance, the night temperature on a city is normally higher than the temperature on rural areas around it. This is known as heat island effect caused by the concentration of buildings, cars, asphalt, etc., typical of urban areas.

Greenhouse gases

After the industrial revolution, the increase of *greenhouse* gases emission has also impacted the climate of the Earth. A small but constant increase of the atmosphere's average temperature has been observed since then as seen in Figure 6. Today's technology for studying climate change makes use of global climate models that are, in simple words, computer programs for solving mathematical equations that describe the circulation of the atmosphere and the oceans. Using such technology, it is possible to infer the climate in the future. Such models estimate an increasing warming climate for the next 100 years if the

Climate Change: Factors Causing Variation or Change in the Climate, Figure 6 Difference between the average Earth surface temperature from 1961 to 1990 and the annual average since 1860 (Source: IPCC, 2001).

Climate Change: Factors Causing Variation or Change in the Climate, Figure 7 Future scenarios of global surface warming relative to six CO₂ emission scenarios (IPCC, 2007) A1: world of very rapid economic growth, population peaks in mid-century, and rapid introduction of new and more efficient technologies. A1F1: A1 with fossil intensive energy resources. A1T: A1 with nonfossil energy resources. A1B balance across all sources. B1: convergent world, with the same global population as A1, but with more rapid changes in economic structures toward a service and information economy. B2: world with intermediate population and economic growth, emphasizing local solutions to economic, social, and environmental sustainability. A2: very heterogeneous world with high population growth, slow economic development, and slow technological change. The gray bars to the right indicate the best estimate (solid line within each bar) and the likely range for the six scenarios at 2090–2099 relative to 1980–1999 (Source: IPCC, 2007).

emissions of greenhouse gases continue as they are today (scenario A2 in [Figure 7](#)). A smaller warming is expected if emissions are reduced (scenario B1 in [Figure 7](#)).

All these mentioned causes for climate change are continuously acting and interacting with each other. The result of such a complex system is that in some periods, they can add on their impacts enhancing them or counteract each other's effects and fading their impacts on the Earth's climate.

COASTAL LAGOONS

Magnus Larson
Department of Water Resources Engineering, Lund
University, Lund, Sweden

Synonyms

Inland coastal water bodies

Definition

Coastal lagoons. Water bodies connected to the sea through one or more channels, known as inlets, which often cuts through a narrow barrier island of erodible material. Water exchange occurs between the lagoon and the sea because of tides, river flow, wind, and waves. Depending on the ratio between the salt water and the freshwater flows taking part in this exchange, stratified conditions may develop and density-driven currents will be important for the mixing and environmental conditions of the lagoon (compare *estuarine hydrology*). Coastal lagoons may close, intermittently or permanently, if the water exchange is not sufficient to keep the inlets free of sediment.

Introduction

Lagoons are common water bodies in many parts of the world and it has been estimated that approximately 13% of the world's coastline is occupied by lagoons (Barnes, 1980). The occurrence of lagoons is rather similar on the different continents, but they tend to be less numerous in Europe (5% of the coastline) and more common in Africa (18%) and North America (18%). The main factor behind the formation of coastal lagoons was the rising sea level during the Holocene in combination with coastal processes acting on marine deposits (Kjerfve, 1986). Coastal lagoons are typically oriented along the coastline and are shallow water bodies with depths often not exceeding a few meters. Lagoons are often strongly influenced by human activities that include multipurpose, often conflicting usages, such as navigation and anchorage, aquaculture, recipient for wastewater and agricultural drainage, and recreation. Since these water bodies in general are sensitive to external water and pollution inputs, the management of lagoons is a complex issue, involving physical, environmental, social, and economical aspects.

Lagoons typically act as deposition basins for sediment and organic matter, which originate either from the sea, adjacent land areas, or discharging rivers (see [Sedimentation Processes in Lakes](#)). Thus, in a geological time frame, the lagoons have a short lifespan, experiencing infilling and closure (Woodroffe, 2002). The availability of sediment and organic matter implies high primary and secondary production rates, which is one reason for the frequent use of lagoons for aquaculture and fishery (Miller et al., 1990). Density variations and *stratification*, primarily due to salinity, although temperature effects may be significant as well, often prevail in a lagoon. However, the conditions in the lagoon may vary from freshwater to hypersaline, depending on the relative importance of the freshwater input from rivers and the water exchange with the sea due to the tide (evaporation could also be a factor in some cases).

There are large variations in the size and general properties of lagoons. Kjerfve (1986) performed a comparative study on coastal lagoons and presented basic data from a number of case studies worldwide. The surface area of the lagoons investigated ranged from 1 to almost 13,000 km², with mean depths being below 5 m in most cases. The lagoons studied experience river inflows from 0 to 4,000 m³/s and tidal ranges from 0.2 to 1.5 m, implying a wide range of salinity characteristics, including cases with fresh, brackish, oceanic, and hypersaline water. This comparative study indicated the importance of inlet channels and how the water exchange occurs through these channels.

Classification of lagoons

Several systems have been developed to classify lagoons depending on the climatology, inlet *hydrodynamics*, salinity conditions, and geomorphology (e.g., Tagliapietra and Ghirardini, 2006). Kjerfve and Magill (1989) divided

lagoons into choked, restricted, and leaky systems, which refer to the characteristics of the exchange flow with the sea. Choked lagoons include only one inlet channel and the ratio between the inlet cross-sectional area (A_I) and the lagoon surface area (A_L) is small. Thus, the renewal time for the water in the lagoon tends to be long and the exchange flow controlled by riverine processes. A leaky lagoon has several inlets and a larger ratio A_I/A_L with the tidal flow typically dominating the exchange between the lagoon and the sea. Restricted lagoons constitute the intermediate case between choked and leaky lagoons.

Carter (1995) also classified lagoons based on the flow characteristics, but used the typical inflow (Q_{in}) and outflow (Q_{out}) rates through the inlet as the main parameters for distinguishing between different types of lagoons. Three cases were identified, namely, $Q_{in} = Q_{out}$, $Q_{in} > Q_{out}$, and $Q_{in} < Q_{out}$. The case where inflow and outflow is the same corresponds to lagoons where tidal exchange dominates, whereas $Q_{in} > Q_{out}$ prevails for hypersaline lagoons where evaporation is a significant component in the water budget for the lagoon. Hypersaline lagoons are common along low-latitude arid coasts. The third case ($Q_{in} < Q_{out}$) occurs when there is a significant relative contribution from river runoff to the lagoon.

Basic mechanisms for water exchange

The physical and environmental conditions in the lagoon are primarily determined by the water exchange with the sea. This exchange includes a number of components that are of varying relative importance, not only between different lagoons, but also over time (e.g., the presence of annual cycles). Main components defining the water exchange is the tidal flow, river flow, direct surface runoff, wind-induced *circulation*, wave-driven currents, and evaporation. In many lagoons, the tidal and river flows are most important for the water exchange and the water quality in the lagoon. An important quantity defining the water exchange due to the tide is the tidal prism (P), which is the volume of water that is exchanged during a tidal cycle (i.e., the volume of water that flows in and out between high and low tide; O'Brien, 1931). It has been shown that the inlet cross-sectional area at equilibrium conditions, as well as different morphological features such as bars and shoals that form around the inlet, may be related to P (Jarrett, 1976; Walton and Adams, 1976).

The simplest type of mathematical model for determining the water exchange includes only tidal flow (Q_I) and river flow (Q_R), neglecting spatial water level differences in the lagoon and treating it as a homogeneous water body. This type of model was first proposed by Keulegan (1967) and it includes two governing equations, namely, water volume conservation for the lagoon and an energy (or momentum) equation for the inlet. The model contains two unknowns, the water level in the lagoon and the velocity through the inlet, whereas the river inflow and the water level variations in the sea are input quantities.

The conservation equation expresses that the change in the lagoon volume is a result of the inflow due to the tide and river discharge:

$$\frac{d}{dt}(A_L \eta_L) = Q_I + Q_R$$

where A_L is the lagoon surface area and η_L is the lagoon water level. The velocity through the inlet may be obtained from the energy equation between the ocean and the bay:

$$\eta_o = \eta_B + k_f \frac{u_I |u_I|}{2g}$$

where η_o is the ocean water level, k_f is a loss coefficient for the inlet, including entrance, exit, and frictional losses. The flow through the inlet is given by $Q_I = u_I A_I$, where A_I is the inlet cross-sectional area, and inflow to the bay is taken as positive. If there is no tide, the flow at equilibrium through the inlet is equal to the river flow ($Q_I = -Q_R$). In general, it is not possible to find an analytical solution to these two equations, but a numerical approach must be taken.

To spatially resolve the flow field inside the lagoon requires more advanced models (e.g., Fischer, 1981; Buttolph et al., 2006). Such models employ the momentum equations together with the volume conservation equation, often using a depth-averaged description since lagoons tend to be shallow and well mixed through the water column. In a depth-averaged model the local water depth and velocities in two coordinate directions are the unknowns. If density-driven flows are of importance for lagoon *circulation*, the flow equations have to be supplemented with equations describing heat or salt transport depending on whether the density differences are due to temperature or salinity, respectively.

Lagoon mixing and residence time

Lagoons are typically recipients for a wide range of pollution discharges and it is useful to quantify the rate at which the polluted water is renewed. A common quantity for characterizing the water renewal in a lagoon is the residence time T_L , which is the time it takes to replace the entire water volume in the lagoon (V_L) with regard to the exchange flow. If only tidal exchange exists then $T_L = V_L/(P/t_T)$, with t_T being the tidal period, whereas if river flow is present $T_L = V_L/(P/t_T + Q_R)$. Although useful, the residence time is a simplistic measure, assuming no mixing between the new water coming into the lagoon and the polluted water, which in many cases does not properly describe the mixing processes. An alternative approach to assess the environmental conditions in the lagoon is through a box model, in which the lagoon water is taken to be instantaneously and uniformly mixed.

A box model involves a mass balance for the lagoon with regard to a certain pollutant, where the lagoon is considered to be one unit with no resolution in space. However, the quantities describing the lagoon are allowed to

vary in time (e.g., flow rate, volume, area, concentration). The mass balance is written for the pollutant under study, and the water flows and volumes are determined through a Keulegan-type model, as described in the previous section. A simple system of equations for a lagoon that is exchanging water with the sea, including river flow, is given by:

$$\frac{d}{dt}(cV_L) = Q_I c_I + Q_{RCR} \quad Q_I > 0$$

$$\frac{d}{dt}(cV_L) = Q_{RCR} - c(Q_I + Q_R) \quad Q_I < 0$$

where t is the time, c the concentration in the lagoon, c_I the concentration in the inflowing sea water, and c_R the concentration in the river water. Note that the outflow will always have the concentration c (after complete mixing in the lagoon) and inflow is taken to be positive. Tidal inflow periods have to be separated from tidal outflow periods.

For a typical lagoon that is exchanging water with the sea only, having no river inflow and neglecting evaporation, and looking over a longer time period, the inflow equals the outflow and there is no change in the water volume in the lagoon. However, the mass balance for a pollutant typically implies changes in the mass of pollutant in the lagoon since c and c_I will have different values (the inflow will have water with a different concentration than the outflow). After these simplifications, the mass balance for the pollutant may be expressed as:

$$\frac{d}{dt}(cV_L) = \bar{Q}_I c_I - c\bar{Q}_I$$

where $\bar{Q}_I (= P/t_T)$ is the average exchange flow through the inlet. Since the lagoon water volume is constant, the equation may be solved to yield:

$$c(t) = c_i \exp\left(-\frac{t}{T_L}\right)$$

where c_i is the initial concentration at time $t = 0$ in the lagoon (e.g., after a pollution release) and $T_L = V_L/\bar{Q}_I$ (residence time). This solution may be used to estimate how long it will take for the concentration of a certain pollutant to decrease to, for example, $1/10 (= c/c_i)$ of its initial concentration due to the water exchange with the sea. Thus, a measure of the water exchange and its impact on the lagoon environmental conditions may be obtained.

An alternative approach to the box model for simulating the water quality in a lagoon is the advection-diffusion (AD) equation (Fischer, 1981). The AD equation describes the spatial and temporal variation in the concentration of a specific pollutant taking into account the main transport and mixing processes such as advection and diffusion (see *Mixing in Lakes*). Also, sources and sinks that add or remove, respectively, material from the lagoon can be included in the AD equation.

Inlet morphology and closure

The water exchange through an inlet typically induces sediment transport into the lagoon during flood tide and out toward the ocean during ebb tide. Simultaneously, on most coastlines with lagoons, waves generate longshore sediment transport that is interrupted by the inlet flow. The interaction between the transport due to the inlet flow and the waves creates morphological features of different types that in turn affect the flow conditions around the inlet. If the longshore transport is large compared to the inlet transport capacity, the inlet cross-sectional area may decrease, which reduces the water exchange. Also, the inlet can migrate alongshore and even close under strong relative longshore transport. Inlet migration (and closure) greatly impacts the water exchange and environmental conditions in the lagoon. In different parts of the world, for example, Australia, Japan, and Sri Lanka, inlets may seasonally close as waves and river runoff greatly vary over the year. Typical features of the seasonally closed inlets are that they occur in micro-tidal, wave-dominated coastal environments where the seasonal stream flow and wave climate variations are large (Ranasinghe and Pattiaratchi, 1999).

CYANOBACTERIA (BLUE-GREEN ALGAE)

Alan Howard

School of Human and Environmental Science, University of Reading, Reading, UK

Introduction

Cyanobacteria (blue-green algae) occur naturally in fresh-water environments including lakes, reservoirs, ponds, and slow-flowing rivers and estuaries. Under enhanced conditions, the cyanobacteria may proliferate and become an unsightly and often poisonous bloom. According to Reynolds (1987), cyanobacterial blooms have done more to give eutrophication its bad name than any other consequence of lake enrichment. The most common bloom-forming genera of cyanobacteria include *Microcystis*, *Anabaena*, *Nodularia*, and *Oscillatoria*.

Biological characteristics

Cyanobacteria are photosynthetic organisms and as such require light (400–700 nm wavelength) and a supply of inorganic carbon to grow. The photosynthetic rate is also affected by nutrient level (particularly phosphorus), water temperature, and water chemistry. For *Microcystis*, the maximum photosynthetic rate of 28.9×10^{-6} (mol C) (mol cell C)⁻¹ s⁻¹ at 20°C is achieved at a photon flux of 753×10^{-6} mol photon m² S⁻¹ (Reynolds, 1990). Certain cyanobacteria such as *Oscillatoria agardhii* are able to increase their photosynthetic efficiency in persistent low light (Reynolds, 1990). The optimum water temperature range for cyanobacterial growth is 25–35°C (Reynolds and Walsby, 1975); blooms generally occur in hard water (Pearsall, 1932) within a pH range of 7.5–9.0 (Kratz and Myers, 1955; Brock, 1973).

The maximum growth rate of *Microcystis* at 20°C is 5.5×10^{-6} S⁻¹ (Reynolds, 1990). If photosynthetic production is greater than this figure, then surplus carbohydrate is stored as ballast. An excess carbon production of 9×10^{-6} (mol C) (mol cell C)⁻¹ s⁻¹ will increase cell density by 1.62×10^{-3} kg m³ s⁻¹. In darkness, stored carbohydrate is used to meet respiratory demand (0.55×10^{-6} [mol C] [mol cell C]⁻¹ s⁻¹),

resulting in density loss. A resultant characteristic of bloom-forming cyanobacteria is that their density varies diurnally above and below that of water (998.2 kg m⁻³ at 20°C), resulting in oscillatory vertical migration patterns. If sufficient density is lost, then the cyanobacteria may migrate to the lake surface and form a concentrated bloom at or near the shoreline. This process is aided by the presence of rigid gas vesicles that give the cyanobacteria additional buoyancy. In some genera such as *Anabaena*, collapse (due to turgor pressure) and light-mediated synthesis of gas vesicles also contribute significantly to density change (Walsby, 1988).

Potential problems

A surface bloom of cyanobacteria may persist if there is a shortage of carbon. Without carbon, photosynthesis cannot occur, meaning that “ballast” accumulation is not possible and the bloom does not sink. Under these conditions, or if the bloom has been transported by wind currents to the shoreline, the bloom may become accessible to water body users. This is potentially dangerous because about 70% of blooms release toxins that can kill animals and cause illness in humans. Exposure to toxins can also cause bioaccumulation in the tissues of fish and shellfish and indirectly affect other organisms through the food chain (Antoniou et al. (2005). The problems and occurrence of toxic cyanobacterial blooms have been reviewed regularly (e.g., NRA, 1990; Chorus and Bartram, 1999; Briand et al., 2003).

In 1996, 100 dialysis patients in Caruaru, Pernambuco State, Brazil, developed acute liver failure apparently caused by intravenous exposure to water supplied from a bloom-affected supply reservoir (Azevedo et al., 2002). Subsequently, in 2000, Brazil incorporated cyanobacteria and cyanotoxin parameters into their drinking water regulations. However, worldwide, national implementation of regulations for cyanobacteria in drinking or recreational waters has been patchy. In the EU, the 2006 Bathing Waters Directive includes direction on the management of “accumulations” of cyanobacteria.

Problem cyanobacterial blooms are not isolated geographically; it is a worldwide water-quality problem that may increase as climate change makes more water environments suitable for cyanobacterial growth. Pearl and Huisman (2009) note that future climatic change scenarios predict rising temperatures and enhanced vertical stratification of aquatic environments which favor harmful cyanobacterial blooms in eutrophic waters.

Future management strategies should consider the impact of global warming on the distribution and growth of problem blooms as well as seeking amelioration through integrated catchment management policies to reduce eutrophication. Artificial mixing devices installed in water bodies can reduce growth by altering the underwater light environment; in some cases, however, this may promote accelerated growth of diatoms and green algae. Short-term solutions such as chemical algicides should be avoided as application may be detrimental to

desirable flora and fauna and may cause a large pulse of growth-promoting nutrient and toxin to be released at once.

DAM FAILURES: IMPACT ON RESERVOIR SAFETY LEGISLATION IN GREAT BRITAIN

J. Andrew Charles
Formerly, Building Research Establishment, Watford,
Hertfordshire, UK

Introduction

“Every dam, regardless of its size, is in some degree a potential menace to everything below it. There is nothing so relentless in its immediate destructiveness, so uncontrollable and deadly as a huge volume of water suddenly released.” This warning, which was given at a symposium in New York on the public supervision of dams (Hinderlider, 1932), forms a necessary reminder that although reservoirs have provided immense benefits to mankind, as with all human progress, there is a price to be paid. Part of that price is the potential hazard of a dam breach when the uncontrolled release of the impounded water can cause enormous property damage, injury, and death. In 1930, the year that the New York symposium was held, comprehensive reservoir safety legislation was introduced into Great Britain in the form of the Reservoirs (Safety Provisions) Act.

British reservoir safety legislation applies to “raised reservoirs,” that is to say it applies where artificially created bodies of water are impounded above the level of the surrounding ground. The legislation does not apply to naturally formed bodies of water such as lakes and lochs, nor does it apply where fluids other than water are impounded. The scope of the legislation is restricted to “raised” reservoirs since reservoirs formed by digging a basin in the ground rather than by building a dam are not normally a threat to public safety. Before considering dam failures and their impact on the development of

safety legislation, the history of dam construction in Great Britain and the current population of dams are briefly reviewed.

Reservoir construction in Great Britain

Reservoir construction has a long history in Britain, and the 70-m-long, 6-m-high earth embankment which forms the “Great Weir” near Alresford in Hampshire was built in about 1200 AD. It has been suggested that the reservoir, which originally covered 80 ha but is now much reduced in extent, formed part of navigation works on the River Itchen, but it is more likely that it was just a fish pond. During the Middle Ages, power to drive water wheels for mills was one of the principal objectives of constructing dams and weirs, and in the seventeenth century, many weirs were built to improve inland navigation.

From the middle of the eighteenth century, it became fashionable for the owners of country estates to have their grounds landscaped, sometimes involving earth moving on a large scale. Capability Brown, the best known of the landscape gardeners of that time, built many small embankment dams, typically 6 m high, to form “lakes” in the grounds of these country estates. In contrast to the earlier mill dams, these lakes were not utilitarian and were formed solely to improve the environment. This has a certain irony in the light of modern environmental opposition to dam construction.

By the end of the eighteenth century, reservoirs were needed to supply the canals being built across the country. The 21-m-high embankment at Todd Brook, west of Whaley Bridge in Cheshire, was the highest late eighteenth century canal dam. Famous engineers, such as Smeaton, Telford, and Rennie were responsible for many canal dams.

Zoning of fill within the embankment represented a major development in embankment dam construction,

Dam Failures: Impact on Reservoir Safety Legislation in Great Britain, Figure 1 Typical cross section of puddle clay core dam. (After Charles and Watts, 1987.)

and central puddle clay cores became the norm in the nineteenth century. Figure 1 shows a typical cross-section of this type of embankment dam. Puddle clay is not a description of a particular type of clay but refers to the way clay was puddled by a process in which the natural structure of the clay was destroyed by remolding and working in extra water. Puddle clay had already been used as an impermeable surface lining for canals, but its use to form the central core of a dam marked a major improvement in embankment design.

During the first half of the nineteenth century, the demand for unpolluted water supplies to the rapidly expanding industrial towns led to a major increase in reservoir construction. This continued throughout the nineteenth and twentieth centuries, but there was a decline in dam building in the 1980s, and very few large dams are being designed and constructed in the twenty-first century. Before 1900, nearly all the reservoirs constructed in Britain were impounded by embankment dams, with a notable exception in Vyrnwy, a gravity dam built in 1890 to supply water to the city of Liverpool. In the twentieth century, a significant proportion of dams were built of masonry or concrete. Early in the twentieth century, construction work began in the Scottish highlands for the production of hydroelectric power, and these reservoirs are mostly impounded by concrete dams.

Some 80% of the current population of British reservoirs is impounded by embankment dams. The highest dam in Great Britain is the 90-m-high rockfill embankment which impounds Llyn Brianne in central Wales, but most embankment dams are quite small and are so much in harmony with their environment that members of the public may be unaware that the reservoir is anything other than a natural body of water. Trees on the crest of an old embankment dam may well enhance the environment, but they can have a less desirable impact on the security of the embankment as illustrated in Figure 2. Wave erosion is concentrated in the areas between the trees, and the trees could be uprooted during storms, seriously damaging the embankment crest.

Instability during embankment construction

A significant number of embankment dams have “failed” in the sense that there was a slip in one of the embankment

Dam Failures: Impact on Reservoir Safety Legislation in Great Britain, Figure 2 Trees on crest of an old embankment dam.

slopes during construction. In July 1937, when 8 m had been completed of the planned 10-m height of the earth embankment for the William Girling storage reservoir at Chingford in Essex, a 90-m-long section of the downstream (outer) slope moved (Cooling and Golder, 1942). The slip surface passed through the central puddle clay core and then followed a path contained within a layer of soft yellow clay in the foundation as illustrated in Figure 3. The Chingford reservoir embankment was one of the first to be built in Britain using what at that time would have been described as “modern earth moving equipment,” and the construction rate was faster than had previously

Dam Failures: Impact on Reservoir Safety Legislation in Great Britain, Figure 3 Instability during construction of embankment of William Girling reservoir, Chingford, in July 1937. (After Cooling and Golder, 1942.)

been common practice. It seems likely that the development of high pore water pressures in the yellow foundation clay due to rapid loading by the embankment was a major contributory factor in the slope instability. During 1937, two other large embankment dams, Abberton and Hollowell, suffered major slips while under construction.

Most of the cases of instability during construction occurred before the full development and application of modern soil mechanics to the analysis of slope stability, but there has been one notable event in more recent times. At the beginning of June 1984, with embankment construction approaching its maximum height of 35 m, a 400-m length of the upstream shoulder of Carsington dam in Derbyshire slipped some 15 m as seen in Figure 4. The investigation of the events at Carsington made important contributions to the fundamental understanding of the behavior of large earthworks of this type (Potts et al., 1990). In his report to the Secretary of State for the Environment, Coxon (1986) made a number of recommendations including the use of review or advisory panels for major dam construction projects.

While a significant number of embankment dams have suffered slope instability during construction, such slips usually have occurred when there was little or no impounded water and consequently there was no threat to public safety. This was the case at both Chingford and Carsington. However, at Carsington, a major reconstruction of the embankment was needed (Banyard et al., 1992).

Dam Failures: Impact on Reservoir Safety Legislation in Great Britain, Figure 4 Instability during construction of Carsington embankment dam in June 1984.

Dam failures in Great Britain

It has been noted that it is only when a dam is breached with a consequent uncontrolled release of the impounded reservoir water that public safety is likely to be compromised. Table 1 shows that some 427 lives have been lost in Great Britain in 14 failure events of this nature.

Failure of Bold Venture Lodge in 1848

One of the earliest instances of a dam failure causing a number of deaths occurred on 23 August 1848 when a small puddle clay core embankment dam at Darwen in Lancashire failed by overtopping during a storm. The

10-m-high dam only impounded $20 \times 10^3 \text{ m}^3$ of water, but the failure resulted in the loss of 12 lives. The verdict of the jury at the inquest was that "... all the deaths inquired into occurred by an accidental cause, that cause being the excessive rains of Tuesday night and Wednesday morning, by which the reservoir at Bold Venture Lodge overflowed and washed away the embankment ..."

A few years later, two dam failures in Yorkshire caused much greater loss of life, and the juries at the inquests made much less charitable judgments as to the causes of

Dam Failures: Impact on Reservoir Safety Legislation in Great Britain, Table 1 British dam failures causing loss of life (After Charles, 1993)

Dam	Height (m)	Reservoir volume (10 ³ m ³)	Date built	Date failed	Deaths
Tunnel End	9		1798	1799	1

Eigiau and	10	4,500	1911	1925	16
Coedty	11	320	1924	1925	

the catastrophes, strongly criticizing owners and engineers rather than attributing the deaths to an “accidental cause.” The failures of Bilberry and Dale Dyke were not directly and primarily attributable to extreme floods, and human culpability, doubtless, seemed more obvious.

Failure of Bilberry in 1852

The collapse of Bilberry dam in February 1852 caused 81 deaths and much property damage in the vicinity of Holmfirth in west Yorkshire (Binnie, 1981). Construction of the puddle clay core embankment dam had been beset with problems. Excavation for the cut-off trench began in 1839, and a spring was encountered in the bottom of the trench. The outlet works comprised a masonry culvert which had to cross the puddle-clay-filled cut-off trench, and serious problems soon became apparent: muddy water came through the culvert in 1841, and in 1843, the leakage became worse, and water burst through the culvert. Remedial works were unsuccessful, and large settlements occurred.

It was claimed that between 1846 and 1851, the embankment settled 3 m, eliminating the freeboard. Soon after midnight on Thursday 5 February 1852, the embankment was overtopped and breached during a storm. The reservoir emptied in 30 min. The unsafe state of the dam had been recognized by many of those living closest to it, and the vigilance of these people enabled them to escape the flood that engulfed many of the inhabitants of Holmfirth who lived lower down the valley.

This was the first dam disaster in Great Britain to draw major attention to reservoir safety, and the Home Secretary, Sir George Grey, arranged for Captain R. C. Moody of the Royal Engineers to inspect the remains of the dam and give expert evidence at the

inquest. It would appear that erosion of and through the puddle clay was the cause of the settlement that led to the catastrophe. Captain Moody remarked that a sink-hole in the crest was located above the culvert “and is no doubt due to the washing away of the bad puddling over and above the culvert where it passes through the puddle wall below.”

At the inquest, the verdict of the jury on Friday, February 27, 1852, contained strong criticism of the dam owners, referring to their “gross and culpable negligence,” and pointed to the need for legislation: “We also hope that the legislature will take into its most serious consideration the propriety of making provision for the protection of the lives and properties of Her Majesty’s subjects exposed to danger from reservoirs placed by corporations in situations similar to those under the charge of the Holme Reservoirs Commissioners.”

A quick legislative response to the catastrophe was made unlikely by the changes in government that occurred in 1852 (Charles, 2002). It was only when Sir George Grey was Home Secretary again, from 1861 to 1866, that he was able to introduce legislation in response to the Bilberry failure. There were nine clauses in the Waterworks Clauses Act of 1863 on the security of reservoirs. Any interested person could make a complaint to two justices of the peace that a reservoir was in a dangerous state. The justices had powers to order the lowering of the reservoir and the execution of works to remove the cause of the complaint.

Failure of Dale Dyke in 1864

The Dale Dyke dam in south Yorkshire failed during first filling of the reservoir in March 1864. Construction work on the 29-m-high puddle clay core embankment dam started in January 1859; the deep puddle-clay-filled cut-off was completed in 1861, and the embankment was finished by April 1863. The cross-section of the embankment in Figure 5 shows that the puddle clay core was unusually thin. Impounding commenced in June 1863, and by March 10, 1864, the water level was 0.7 m below the crest of the weir. In the late afternoon of the following day, a crack was observed along the downstream slope near the crest of the dam. An attempt was made to blow up the overflow weir, but before this was achieved, the dam breached on the night of Friday, March 11, 1864, at 11.30 p.m.

The reservoir, which was close to the village of Bradfield, was far larger than Bilberry, and the catastrophe claimed 244 lives in the vicinity of Sheffield. This is the most serious dam failure that has occurred in Great Britain and has a strong claim to be regarded as the country’s worst civil engineering disaster. The Home Secretary, Sir George Grey, appointed two civil engineers, Robert Rawlinson and Nathaniel Beardmore, to report on the “failure and bursting” of the reservoir embankment.

A leader in *The Times* on 17 March 1864 argued that those threatened by reservoirs could not be expected to defend themselves and needed protection. There was pressure for a government inspectorate, and the verdict of the

Dam Failures: Impact on Reservoir Safety Legislation in Great Britain, Figure 5 Cross section of Dale Dyke dam. (After Binnie, 1981.)

jury at the inquest on Thursday 24 March referred to the lack of engineering skill and inadequate attention to the construction of the works and recommended that: "... the Legislature ought to take such action as will result in a governmental inspection of all works of this character; and, that such inspections should be frequent, sufficient, and regular."

In their report to the Home Secretary, Rawlinson and Beardmore (1864) were critical of both the design and the construction of the dam. They believed that failure was most likely to have been caused by leakage from a fractured outlet pipe, but the design and construction of the embankment was also criticized: "... the puddle-wall is much too thin, and the material placed on either side of it is of too porous a character, ... No puddle-wall should ever be placed betwixt masses of porous earth, as puddle, under such conditions, will crack, and is also liable to be fractured by pressure of water."

However, Rawlinson and Beardmore did not endorse the jury's recommendation for government inspection because: "Any approval of plans or casual inspection of waterworks embankments cannot ensure ultimate safety in such works. The responsibility must remain, as at present, with the engineer and persons immediately connected with the works. Magistrates have jurisdiction under clauses inserted in recent Waterworks Acts."

The Waterworks Bill 1865/1866

On 23 February 1865, Sir George Grey announced that legislation was being prepared. The bill was referred to a select committee of the House of Commons, which reported on 23 June 1865. While emphasizing that it did not intend to diminish the responsibility of the owners or operators ("undertakers") of waterworks to pay damages, the Committee made the following recommendations:

- When it is proposed to construct a large reservoir, the undertakers should submit to the appropriate government department plans and sections of the reservoir site

and the proposed works, together with descriptions of the mode of construction.

- The government department should send a competent engineer to inspect and report on the works that are to be constructed.
- When the reservoir is completed, the undertakers should give due notice to the government department, and the reservoir should not be filled with water until the specified time has expired.
- Adequate supervision over all large reservoirs should be maintained by the government department, and competent engineers should be sent to inspect and report on such reservoirs from time to time.

A new bill was introduced in parliament in 1866, largely following the recommendations of the Select Committee and including a clause imposing strict liability. It was restricted to reservoirs impounding over a million cubic feet of water ($28 \times 10^3 \text{ m}^3$). However, the Waterworks Bill of 1866 ran out of time, and following a change in government, in February 1867, it was announced in parliament that there was no intention of reintroducing the bill.

Failures of Skelmorlie and Eigiau/Coedty in 1925

Sixty years after the Select Committee made its recommendations, two further reservoir failures occurred, the first in Scotland and the second in Wales. Following heavy rainfall, the Skelmorlie lower reservoir in south-west Scotland failed at 2 p.m. on Saturday 18 April 1925. The floodwater, which was probably sufficient to overtop the embankment, was augmented by water from a quarry, which having partially filled due to a blocked culvert, suddenly emptied when the blockage cleared. The embankment was breached over a 9-m length, and the reservoir emptied in 15 min. Five people were killed in the village of Skelmorlie. The failure was attributed to a grossly deficient overflow and inadequate freeboard, and the verdict of the jury at an inquiry held at Kilmarnock

Sherriff Court was that: “The disaster was caused by absence of any regular skilled supervision and inspection.”

An even more serious event occurred 6 months later in Wales. The small mass concrete gravity Eigiau dam, which had been built between 1907 and 1911 and which impounded a reservoir with a volume of $4.5 \times 10^6 \text{ m}^3$, breached at 8.45 p.m. on Monday, November 2, 1925. At the location of the failure, the structure is only 5 m high as shown in the cross-section in Figure 6. The failure was caused by the blowout of a 10-m-long section of the dam wall; poor concrete and an inadequate foundation depth were contributory factors in the failure. An arch of concrete remained above the breach. Some $1.5 \times 10^6 \text{ m}^3$ of water was discharged through the breach in the hour following the failure, lowering the reservoir by 1.5 m.

The Coedty embankment dam, which was situated 2.5 miles downstream of the Eigiau dam, only impounded $0.3 \times 10^6 \text{ m}^3$ of water, and the water flooding in from the Eigiau reservoir filled the almost full Coedty reservoir within minutes. The dam was overtopped, and the concrete core wall collapsed. A wave of water and mud hit the village of Dolgarrog at 09.15 p.m. Providentially, most of the villagers were watching the weekly film show in the Assembly Hall, situated on high ground. However, ten adults and six children died in this disaster.

Dam Failures: Impact on Reservoir Safety Legislation in Great Britain, Figure 6 Cross section of Eigiau dam at failure location. (Based on Engineering News-Record, 1926.)

Technical evidence at the inquest was given to the effect that the foundation of the Eigiau dam had not been sufficiently deep. The jury returned a verdict of accidental death: “caused by the bursting of the dam under the wall in consequence of the wall lacking a proper foundation.” The coroner’s jury recommended regular government inspection.

The Coedty embankment dam was repaired, but the Eigiau concrete dam was not rebuilt; Figure 7 is a recent photograph of the breach. The concrete arch, which initially bridged the ruptured area, was blown up, facilitating the post-failure inspection of the cross-section on either side of the breach.

Following this failure, a leading dam engineer, Edward Sandeman, wrote to *The Times*, and his letter was published on Friday, December 4, 1925. It commenced: “In view of the loss of life following upon the failure of the dams of reservoirs in Scotland and North Wales recently, I beg to call your attention to the report made by the Select Committee on the Waterworks Bill 1865 (Sessional Paper 401), after they had considered the evidence as to the failure of the earth embankment of the Bradfield Reservoir on March 11, 1864, when 245 lives were lost.”

Sandeman commented that it was “unfortunate” that some such control as was then suggested had not been brought into effect and pointed out that there was a vital need to investigate the ability of the reservoirs of the country, firstly, to withstand the pressures to which they are subjected in normal operation and, secondly, to assess whether their overflows were of sufficient capacity to deal with floods caused by the exceptionally heavy rainstorms which had occurred in the previous 15 years.

Having made reference to earth embankment dams which had sunk in the center to such an extent that they were in a dangerous condition and to overflows which had been interfered with and altered to a dangerous extent, Sandeman concluded that “These instances alone are sufficient to show that inspection of existing reservoirs is necessary. In the interests of the public safety it is of importance that the matter should receive attention without delay.”

Reservoirs (Safety Provisions) Act 1930

Government legislation on reservoir inspection was implemented, but not without further delay! 5 years after Edward Sandeman’s letter was published in *The Times* and following a change of government in 1929, the Reservoirs (Safety Provisions) Act 1930 became operative on 1 January 1931. It was described as: “An Act to impose, in the interests of safety, precautions to be observed in the construction, alteration, and use of reservoirs, and to amend the law with respect to liability for damage and injury caused by the escape of water from reservoirs.” Some of the main requirements of the legislation, which was applicable to reservoirs holding more than five million gallons ($22.7 \times 10^3 \text{ m}^3$), were as follows:

- Design and supervision of construction by a qualified civil engineer

Dam Failures: Impact on Reservoir Safety Legislation in Great Britain, Figure 7 Breach in Eigiau concrete gravity dam.
(Reproduced by permission of Dr Paul Tedd.)

- Reservoir not to be filled until a qualified civil engineer has issued a certificate
- Inspection by a qualified civil engineer at intervals of not more than 10 years
- Undertakers (owners or operators) to keep a record of water levels, leakages, and settlements

A qualified civil engineer was defined as a civil engineer who was a member of a panel constituted for the purposes of the Act. With the advice of the President of the Institution of Civil Engineers, two panels of qualified civil engineers were formed: a panel of engineers qualified to design and supervise construction and inspect all reservoirs to which the Act applied and another panel of engineers qualified only to inspect reservoirs.

In 1946, a four-panel system was introduced. Engineers in all four panels could act as the construction engineer as well as inspect reservoirs, the differences in the panels now related to the type of reservoir: panel I was for all reservoirs and the other three panels were restricted to various types of non-impounding reservoirs. Admission to the panels was at the discretion of the Home Secretary after consultation with the President of the Institution of Civil Engineers who initially set up a small informal advisory committee. It was only in 1965 that a special committee was formally constituted by the Institution for this purpose.

Reservoirs Act 1975

Since the implementation of the 1930 Act, there have been no dam failures in Great Britain causing loss of life, and in view of the link between catastrophic failures and the

demand for legislation, further legislation might have seemed unlikely. Nevertheless, failures and serious incidents continued to occur, and it was known that many other countries were reviewing their regulations. Against this background in 1964, the Institution of Civil Engineers formed a committee which in 1966 published recommendations for amending the law on reservoir safety (Institution of Civil Engineers, 1966).

The Reservoirs Act 1975, which received Royal Assent on 8 May 1975, repealed the Reservoirs (Safety Provisions) Act 1930 and re-enacted the legislation on reservoir safety in a strengthened and more effective form. The content of reservoir safety legislation was greatly expanded by the new Act. Although it was expected that most of its provisions would be brought into force some time before the end of 1975, the Act was only implemented between 1983 and 1987.

The 1975 Act applied to “large raised reservoirs,” that is, reservoirs designed to hold or capable of holding more than 25,000 m³ of water above the natural level of any part of the land adjoining the reservoir. This volume is about 10% greater than the five million gallons specified in the 1930 Act. The Act together with associated Statutory Instruments provided a legal framework within which qualified civil engineers make technical decisions relating to the safety of reservoirs. In effect, the legislation imposed a system of safety checks on reservoir construction and operation.

The 1975 Act kept the same approach to reservoir safety as the 1930 Act in maintaining the panel system of qualified civil engineers but created the new role of supervising engineer. The Act recognized four types

of persons or organizations with distinct functions and responsibilities:

- Undertakers with duties as owner or operator
- Enforcement authorities to ensure compliance with legislation
- Qualified civil engineers to advise on safety
- A government department as legislator

While the 1975 Act embodied most of the recommendations of the 1966 report of the Institution of Civil Engineers committee, there were some significant exceptions: a requirement for undertakers to have third-party insurance was not introduced and the Act was not extended to structures storing liquids other than water. Central control of records and enforcement was not introduced, and enforcement was delegated to local government. A major step toward the central control of enforcement of the Act was taken when the Water Act 2003 transferred the role of enforcement authority in England and Wales from 136 local authorities to the Environment Agency. This transfer took place in October 2004.

Flood and Water Management Act 2010

Despite the excellent record of public safety since reservoir safety legislation was introduced and the undoubted fact that subsequent legislative changes have improved reservoir safety, serious incidents have continued to occur (Wright, 1994). During a flood on 25 June 2007, a serious incident at Ulley puddle clay core embankment dam near Rotherham in south Yorkshire threatened public safety. Although the dam did not breach and there was no uncontrolled release of reservoir water, the failure of the stepped masonry spillway and the associated erosion of the downstream shoulder fill shown in Figure 8 resulted in precautionary measures in which the M1 motorway

was closed for 2 days and 1,000 people were evacuated, although some of these were evacuated as a result of flooding already being experienced (Hinks et al., 2008). A post-incident review of this serious incident identified three areas where action was needed (Mason and Hinks, 2009):

- Development of a better understanding of the defective behavior which caused the incident
- Improvement of preparedness for emergency situations
- Enhancement of a reservoir surveillance culture

In his review of flooding, Sir Michael Pitt (2008) recommended that “The Government should implement the legislative changes proposed in the Environment Agency biennial report on dam and reservoir safety through the forthcoming flooding legislation.” These Environment Agency proposals included moving to a risk-based definition for reservoirs within the ambit of legislation and mandatory post-incident reporting.

While maintaining the panel system of qualified civil engineers for the inspection and supervision of reservoirs, the Flood and Water Management Act 2010 includes provisions for a new risk-based approach to reservoir safety. The new legislation means that a substantial number of small dams which are not considered to be high risk, since failure would have no serious consequences for public safety, can be removed from the onerous requirements of the safety regime. This change is appropriate since a preliminary estimate indicated that about one third of the total population of reservoirs within the ambit of the 1975 Reservoirs Act may not present a significant threat to lives in the event of a dam breach (Charles and Tedd, 2000). Much more importantly, small reservoirs which could endanger human lives, but which were outside the scope of the 1930 and 1975 Acts, can be brought into the new

safety regime which may require all owners of a reservoir impounding more than 10,000 m³ of water to register their reservoir.

The Flood and Water Management Act gained Royal Assent on April 8, 2010, but in May, there was a change in government. At the time of writing, it is not yet clear in what stages and on what time scale the new legislation will be implemented. The Act extends to England and Wales; separate legislation has been drafted in Scotland.

Concluding remarks

The development of British reservoir safety legislation over a period of more than a 100 years has largely been in response to failures and serious incidents. Under this legislation, the ultimate responsibility for reservoir safety lies with owners, and there is a marked absence of direct control by central government. The legislation provides a framework within which independent qualified civil engineers make technical decisions relating to reservoir safety, and great reliance is placed on the competence of these engineers. The legislation contains no technical standards, and appropriate technical guidance has been provided in the form of engineering guides which are listed in "A Guide to the Reservoirs Act 1975" (Institution of Civil Engineers, 2000).

Half the reservoirs which came within the 1975 legislation were built prior to 1900, and Figure 9 shows how over the last 200 years the total storage capacity of British reservoirs has steadily increased, particularly since 1950. With the massive increase of impounded water, there is a much greater potential for loss of life and damage resulting from dam failures, and with an ageing population

of embankment dams, there is no room for complacency, despite the fact that since the 1930 Act came into force no deaths have been reported due to dam failures and the safety record since 1930 has confirmed the general soundness of the British approach to reservoir safety legislation.

The legislation enacted in 2010 introduces a risk-based regime for reservoir safety in contrast to previous legislation where the criterion for a reservoir to come within the ambit of safety legislation was solely based on the impounded volume of the reservoir (five million gallons in the 1930 Act and 25,000 cubic meters in the 1975 Act). Despite this sensible change, future reservoir safety will continue to largely depend on maintaining the professional and technical standards of qualified civil engineers, and continuing vigilance at each reservoir will require appropriate levels of surveillance and, where necessary, upgrading old dams to acceptable current standards.

DAMS AND RESERVOIRS IN MACEDONIA

Ljubomir Tančev
 University “Sts Cyril and Methodius”, Skopje,
 Republic of Macedonia

Introduction

The Republic of Macedonia is located in the central part of the Balkan Peninsula, in the area between 20°27' and 23°01' longitude East (East from Greenwich) and 40°51'

and 42°21' latitude North. It covers an area of 25,713 km² with a population of about two million inhabitants. Its mountain relief, vast valleys, and numerous long and narrow ravines distinguish the topography of the Republic of Macedonia (RM). The territory of the country is under the influence of the modified Mediterranean type of climate resulting from the Continental, Middle European, and dry Eastern climate influences and the influence of the mountain climate, as well as the secondary factors – relief and elevation. As a result of the climate corridors, the relief in the inland area, and its high latitude, there is a great spatial variability of different climatic parameters: rainfall, temperature, air pressure, winds, low humidity, and other factors significant for the water regime.

For the people in the RM, agricultural production has been, even for ancient times, the basic source of existence. The first agricultural civilization in Europe has been existent on Macedonian land some 10,000 years ago. In order to fight droughts, and at the same time to protect themselves from floods, the farmers associated themselves in different ways. They tried jointly to capture the surface water and convey it to the arable land or to make primitive embankments in order to defend themselves from the destructive power of floods (Dodeva, 1999). After the World War II, special priority was given to water and water management, especially by using artificial reservoirs. At that time, within a relatively short period, plans were elaborated for the water management development, respectively for irrigation, drainage, hydropower, flood control, etc.

Surface water – rivers

According to the hydrographical division, the rivers in the RM belong to three main river basins:

1. The Aegean basin, in which they flow out through the rivers Vardar and Strumica
2. The Adriatic basin, to which they are taken away through the river Crn Drim (Black Drim)
3. The Black Sea basin, through the river Binachka Morava, which extends over a quite insignificant part

The biggest is the catchment basin of the river Vardar, which extends to some 20,525 km² or 80% of the territory of the RM.

Total annual available surface water resources in the RM are assessed as 6,372 billion m³, which lead to about 3,300 m³ per capita annually.

Precipitation

The annual average precipitation in the entire state is approximately 730 mm/year, but it ranges from 380 mm in some parts of Eastern and Central Macedonia, up to 2,000 mm in some mounting regions of Western Macedonia. The distribution of the rainfall is very unfavorable in space and time and relatively small in quantity, as a result of the Continental climate and the

Mediterranean influence. The uneven distribution of the rainfall in time and space results in long dry periods (summer–autumn) and shorter winter periods. On the other hand, there is abundant rainfall between October and December and limited rainfall between March and May. Such a distribution of the precipitations, together with the other meteorological phenomena, categorizes the RM as a semi-arid area.

Water demands

The total water demand in the country is 2,030 million m³ annually. Dominant user of the water is the irrigation with 900 million m³ (46%), then minimum accepted flows with 635 million m³ (28%), follows industry with 275 million m³ (14%), and drinking water supply of the population and tourists with 220 million m³ (12%).

The use of water for electricity production, which is closely connected with the reservoirs, is also very important, taking into account that it is a renewable and adaptable energy resource. Total hydropower potential of the RM is estimated on 5,200 GWh, and currently only 27% or 1,500 GWh is used, with an installed power of 530 MW. Depending on the hydrological conditions, the hydropower covers from 10% to 19% of the total energy demands in the country. The annual production in 2000 was 1,170 GWh; in 2001, 621.5 GWh; in 2002, 755.4 GWh; and in 2003, 1,370 GWh. Among ten existing hydropower plants (HPP) on the large reservoirs, the most important are: Vrutok (27% of total production), Shpilje (24%), Tikves (17%), Globochica (15%), small HPPs (11%), Vrben (3%), and Raven (3%). It is interesting to note that the HPP Vrutok, Raven, and Vrben are units of one cascade system, which is supplied with water from the reservoir *Mavrovo* (Dodeva, 2004).

Dams and reservoirs in the Republic of Macedonia

The construction of dams with reservoirs in the Republic of Macedonia dates from 1938, when the *Matka* arch dam was built located on the river Treska, in the vicinity of Skopje. The purpose of this dam with a 3.55-million-m³ reservoir volume has been electricity production (installed capacity $N_i = 3,2$ MW), and it is still in service. Until now, 20 large dams have been built which enclose impounding reservoirs, Figure 1 and Table 1, as well as around 120 small dams, forming reservoirs with volume lower than 500,000 m³. The golden period for reservoir construction was 1952–1972, when 13 important reservoirs were formed by large dams: *Mavrovo*, with dam height of 54 m; *Globochica* (82.5 m); *Vodocha* (42 m); *Tikvesh* (104 m); *Kalimanci* (85 m); *Shpilje* (101 m); *Turiya* (77.5 m); *Lipkovo* (29.5 m); *Gratche* (29 m); *Mladost* (27 m); *Prilep* (35 m); *Ratevska Reka* (49 m); and *Glaznja* (71.5 m). Up to 1982, four new dams with large reservoirs were commissioned, the largest and most important between them being *Strezevo* ($H = 76$ m), especially important for the region of the city of Bitola. During the last 15 years, the reservoir construction was again intensified, resulting to the finishing of the projects

Kozyak ($H = 114$ m, the highest dam in Macedonia) and *Lisiche* (66 m). Recently, the construction works on the projects *Saint Petka* and *Zletovica* have started. The dams *Kozyak*, *Tikvesh*, and *Shpilje* are the largest projects of this type, enclosing reservoirs with volume range of a half billion m³.

Different kinds of dam sites are presented in the RM concerning the geological, topographical, and hydrological conditions. That is why between the built dams there are both concrete and embankment dams. Most of the large dams with reservoirs – 13 – were constructed of local materials: clay, sand, gravel, and rock, while 6 dams were constructed as concrete arch dams and only 1 as concrete multiple-arch dam.

The stored water is used for meeting the demands for water supply of population and industry, irrigation, production of electricity, flood and erosion control, provision of minimum accepted flows, recreation, and tourism. The total stored volume of water in the Macedonian reservoirs is about 2.4×10^9 m³. The small reservoirs, formed nearly in all cases by earth-fill dams, are built mainly during the last 40 years. Its main purpose is to provide water for irrigation.

The most important reservoirs formed by large dams in the RM are (Tančev, 2003; Tančev, 2005):

Matka (*St. Andrea*) – the first artificial lake in Macedonia (1938, 3.55 million m³), formed by an arch concrete dam (29.5 m high), located in the exit of the river Treska from a picturesque narrow gorge, Figure 2. All structures, together with the reservoir, are very well adapted to the terrain and to the nature. The purpose of the reservoir is electricity production, with the installed capacity of the power plant of 3.2 MW, not small for the period just before the World War II. After the refurbishment recently done, the installed capacity was doubled. The reservoir serves also for recreation of the citizens of the nearest city Skopje.

Mavrovo – very important lake, at altitude of 1,200 m. a.s.l., formed with the first Macedonian embankment dam, built in the period 1947–1953. The reservoir volume is more than 300 million m³, while the maximum depth is around 50 m. It gains water not only from the own catchments area but also from the adjacent catchments area of the river Radika, through a specially built water-supplying tunnel. It serves mainly for electricity production by means of three power plants (more than 400 million kWh per year) and also for recreation, tourism, and fishing. The mountainous environment surrounding the lake is extremely nice.

Vodocha – built on the river having the same name (1965), with reservoir surface area of 1.94 km² and volume of 26.7 million m³, formed by an earth-rock dam, 44 m high. The purpose of the reservoir is irrigation, but it serves also for fishing and recreation of the citizens of the neighboring town of Strumica.

Prilep – a reservoir with volume of 6 million m³, formed by a unique multiarch buttress dam, 35 m high. The main aim of the reservoir is irrigation of the famous tobacco fields surrounding the town of Prilep.

Dams and Reservoirs in Macedonia, Figure 1 Large dams with reservoirs in the Republic of Macedonia (After Tančev, 2005).

Tikvesh – one of the largest Macedonian reservoirs (total volume 475 million m^3 , length 22 km), formed by an earth-rock dam, 104 m high, built in 1968 on the River Crna, the largest tributary of Vardar. This reservoir, aimed for electricity production and irrigation of the agricultural fields in the central part of Macedonia, is of great importance for the state economy. The lake is rich with different kinds of fish – examples of carps and spearfish up to 100 kg have been caught.

Kalimanci – the largest reservoir in the Eastern Macedonia, with volume of 127 million m^3 , formed by an earth-rock dam 85 m high, damming the river Bregalnica, the most important left tributary of Vardar. This reservoir has a key role in the agriculture of this dry region, irrigating the fertile fields near the towns of Kochani, Shtip, and Sveti Nikole. A small power plant also is in operation.

Shpilje – one of the three largest Macedonian artificial lakes ($V = 520$ million m^3), located on the river Crn Drim, near the Albanian border. The river Crn Drim flows out from large natural Ohrid Lake. By means of a simple regulating structure, Ohrid Lake is an excellent compensation basin for the two downstream power plants with artificial reservoirs: Globochica ($V = 58$ million m^3) and Shpilje. The mean annual electricity production of Shpilje plants is around 300 million kWh. The reservoir is rich with fish, mainly carp. With the high dams Globochica and Shpilje, as well as with the three dams on the river Drim in Albania, the migration path of the eels from Ohrid Lake to Sargasso Sea has been broken.

Ratevska Reka – located in the mountainous Eastern region, formed with a double curvature arch concrete dam 49 m high, near the town of Berovo, at an elevation

of around 1,000 m.a.s.l. It serves for water supply, irrigation, and recreation.

Turiya – with volume of 48 million m³, closed by means of an earth-rock dam 77.5 m high, enables the water supply of the town of Strumica, as well as irrigation of the

rich surrounding fields. Secondary purposes of the reservoir are electricity production in a small power plant and fishing.

Glaznja – located on the river Lipkovska (the nearest city Kumanovo), formed by the highest concrete dam in

the RM (71.5 m). The reservoir volume is 22 million m³. Commissioned in 1972, it has served for water supply, irrigation, and electricity production (in a small power plant).

Mantovo – a key structure in the frame of the irrigation system, having the same name. The reservoir volume is 47.5 million m³, formed by an earth-rock dam 37.5 m high, very important for the agriculture of the region of Radovich.

Strezevo – a large reservoir (109 million m³), formed by damming the river Shemnica with an earth-rock dam, 76 m high. The reservoir is a part of a modern hydrosystem, aimed for irrigation of more than 20,000 ha of agricultural field in the plain Pelagonija, water supply for the city of Bitola and the adjacent large thermo-power plant, and electricity production in two small power plants.

Kozyak – located some 16 km upstream from the first reservoir built in the RM, Matka (St. Andrea, 1938). Commissioned in 2004, this reservoir is a key structure of the multipurpose scheme with the main task of flood control, with retention storage of 100×10^6 m³. Also, it serves for electricity production (152×10^6 kWh per year), as well as for water supply. The total reservoir volume is 550 million m³, formed by Kozyak Dam, an earth-rock dam, the highest in the RM (114 m above the terrain, 130 m above the foundation). The dam site is narrow, with valley slopes of 1:1 and 1:1.5, respectively. The dam body is built from rock-fill (limestone), taken from the quarry near the dam, while the waterproof element is in the form of slightly inclined core. Due to rather unfavorable geological conditions in the zone of the reservoir, as well as in the dam site (presences of carstified limestone, faults, and so on), extensive grouting works have been performed to reduce the seepage.

Lisiche – with a volume of 23.4 million m³, closed by means of an earthen dam 66 m high, commissioned in 2009. In the first stage, it enables the water supply of the town of Veles. In the second stage, irrigation of the surrounding fields is planned.

Maintenance and operation

The large dams and their reservoirs are operated by different operators depending on the main use of the stored water. The public utility “ELEM” is responsible for operation of the reservoirs the main purpose of which is energy production, while other dams are mainly operated by the public Water Economy Enterprises, Agro-combine, or private Water Organizations. During the whole period of almost 70 years of construction and service of dams and large reservoirs in the RM, there was no serious incident, despite of the chronic lack of funds for maintenance and reparation. Monitoring and surveillance have been performed continually, but a lot of devices are out of use and have to be repaired or replaced.

Environmental impact

The major number of dams and reservoirs were constructed more than 35 years ago, which presents a sufficient period of time for assessment of the

environmental impact. The analyses and the assessment are rather positive due to the location of dams and applied technical solutions. The dams are mainly located in the upstream section of the rivers, in the mountains where there were no populated areas, or significant industrial or economic facilities. With small exceptions, there was no need for large resettlement of the population or facilities. Also, applying appropriate technical measures, the alternative paths were provided for the aquatic species. The situation is similar with the new planned dams. All of them should be constructed in non-populated areas; no significant size of irrigable lands, facilities, or cultural and historical monuments should be flooded; and no specific or protected species would be endangered. The Environmental Impact Assessment Study is a legal obligation as part of the Feasibility Study documentation.

Future plans

According to the national planning documents Water Master Plan and Spatial Plan, more hydropower projects have been planned (all with large dams and reservoirs), the majority of them being: *Sveta Petka*, river Treska, $H = 50$ m, 36 MW, 53 GWh/year (under construction); *Boshkov Most*, river Jadovska, $H = 45$ m, 70 MW, 127 GWh/year; *Chebren*, river Crna, $H = 192$ m, 150 MW, 286 GWh/year; *Gradec*, river Vardar, $H = 42$ m, 55 MW, 252 GWh/year; *Galishte*, river Crna $H = 140$ m, 195 MW, 257 GWh/year; and *Lukovo Pole*, 103 GWh/year.

Two of these reservoirs, *Chebren* and *Galishte*, will serve also for irrigation. To meet the increased demands for different purposes, another large dams with reservoirs are planned, as *Knezevo* (main structure of the multipurpose hydrosystem “Zletovica”), $H = 75$ m (the dam is already finished, the reservoir filling is planned for the Autumn 2011); *Vakuf*, river Kriva Reka (multipurpose); *Razlovci*, river Bregalnica, irrigation; *Konjsko*, river Konjska, irrigation; *Plavaja*, river Plavaja, irrigation; *Buchin* (multipurpose); and *Paligrad*, river Kadina Reka (multipurpose) (Tančev and Petkovski, 2006).

Damming the rivers and forming large reservoirs, two major axioms are always under consideration of dam designers in the RM: The development must respect the principle of sustainability, and the environment has to be protected from possible negative effects. By fully respecting these two major axioms and using our own experience, as well as the experience of the developed countries, the future generations may enjoy the benefits of clean, well preserved, wisely utilized, and planned water resources (Dodeva, 1999).

DAMS AND RESERVOIRS, ROLE

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

There is no life on earth without water, our most important resource apart from air and land. During the past three centuries, the amount of water withdrawn from freshwater resources has increased by a factor of 35, while the world population by a factor of 8. With the present world population of 6.8 billion still growing at a rate of about 90 million per year, and with their legitimate expectations of higher standards of living, global water demand is expected to rise by a further 2–3% annually in the decades ahead.

Meeting water demand by dams and reservoirs

Freshwater resources are limited and unevenly distributed. We cannot forever try to meet insatiable demands by continuously expanding a supply that has limits. In the high-consumption countries with rich resources and a highly developed technical infrastructure, the many ways of conserving, recycling, and reusing water may more or less suffice to curb further growth in supply. In many other regions, however, water availability is critical to any further development above the present unsatisfactorily low level, and even to the mere survival of existing communities or to meet the continuously growing demand originating from the rapid increase of their population. In these regions, man cannot forego the contribution to be made by dams and reservoirs to the harnessing of water resources.

Storage and release

Seasonal variations and climatic irregularities in flow impede the efficient use of river runoff, with flooding and drought causing problems of catastrophic proportions. For almost 5,000 years, dams have served to ensure an adequate supply of water by storing water in times of surplus and releasing it in times of scarcity, thus also preventing or mitigating floods. In response to enormously increased demand, more than half of ICOLD's registered 39,000 large dams have been built in the past 40 years. They have become an integral part of our technical infrastructure, and throughout the world, they enhance the basis

of life by offering many indispensable benefits. Still more dams will be needed in the future for the adequate management of the world's limited, unevenly distributed, and, in many places, acutely scarce water resources.

The need for dams and reservoirs

The need for dams and reservoirs applies in particular to the developing regions of the world, which account for 70% of the world population, and for no less than 94% of annual population growth. There are one billion people suffering from chronic undernourishment or plain starvation, with between 10 and 15 million children dying of hunger every year. About 1.5 billion people have no access to a reliable source of drinking water, and more than two dozen countries have not enough water to sustain their populations properly. Millions die from water-related diseases every year. The result is an exodus of the impoverished rural populations to the even greater inhumanity of the vast shanty towns surrounding the big cities. Of the 22 cities which will have more than 10 million inhabitants by the end of the century, 18 will be in developing countries.

The need for irrigation

In many countries, increased food production is only possible through improved or increased irrigation. At the present time, about 250 million hectares of land is under irrigation, growing one third of our food on less than one fifth of the world's cultivated area and accounting for almost three quarters of world water consumption. In conjunction with great efforts to develop effective ways of saving water by avoiding losses in the distribution systems and by applying more skillful irrigation techniques, UNDP (the United Nations Development Programme) is aiming at a 3% compound rate of growth in irrigated agriculture to meet the needs of an extra one billion people in the next 10 years. Half of them will be city dwellers with a concentrated drinking water requirement. Since the groundwater reservoirs presently tapped to provide about half of irrigation, drinking, and industrial water supply are already heavily overdrawn in many parts of the world, the only large-scale solution apart from saving water is to increase the share of surface water from storage reservoirs.

The quantity of irrigation water required to produce a crop under reservoir conditions depends on a number of factors, such as the natural rainfall and other climatic conditions, type of crop, length of growing season, method and scheduling of irrigation, and soil properties. Several methods for estimating crop water requirements are in use in different countries, but they are usually suitable only for the condition under which each was developed.

Environmental effects

Environmental effects are of increasing concern in the role of dams and reservoirs. The creation of reservoirs usually has a very important influence on ecology. In the case where the storage volume is large in relation to annual

runoff, eutrophication can have a significant impact on the quality of the water in the reservoir because of long residence times. The reservoir exerts a great influence on the temperature and oxygen content of the release water. The regulation of flow will also change the nature of land use downstream of the reservoir. The increase in water use usually results in an increase in the amount of waste water that may lower the quality of water in the receiving river.

Changes of this nature are of major concern. However, reservoirs also cause changes that have beneficial effects. In many cases, the environment in the vicinity of reservoirs and downstream has been greatly improved by providing recreation, esthetic, ecological, and health benefits. It is of primary importance to assess continuously all environmental effects of storage reservoirs and to provide monitoring facilities for measuring environmental factors both before and after construction.

Purposes to be served by dams and reservoirs

In the usual scheme of development for a river basin, all flow which can be suitably regulated is utilized. The available water is divided among requirements in accordance with a system of priorities. Requirements with highest priority are satisfied at all times if possible, while others are served only when sufficient water is available.

Criteria used in the design and operation of dams and reservoirs are usually based on obtaining the maximum net benefits with the resources invested in the project. A design to meet the full demand need not always be the most desirable alternative. Supplies can only be made available at a unit cost which usually increases as the supply grows and can, at some point, exceed the loss resulting from the reduced efficiency of an undersupplied facility. Conflicts can also occur among the various intangible aspects arising, on the one hand, by making supplies available and, on the other, by curtailing demands. It is the objective of water resources management to seek an optimal balance between water supplies and demands by quantifying, to the extent possible, the consequences of trade-offs between the conflicting tendencies on the basis of cost-benefit studies and other considerations.

Multipurpose reservoirs

With the increasing level of development of water resources throughout the world, it is becoming more and more important to plan projects which can serve a number of purposes simultaneously. For example, a planned storage reservoir may provide both water supply and flood control downstream. Hydrological data required for the design of a multipurpose project are basically an aggregate of the data required for the various single purposes involved. The methods of analysis, although similar to those applied in design of single-purpose reservoirs, are more complex. A series of plans involving combinations of project sizes and methods of operation are made to determine the optimum plan.

There is a basic conflict between the management of water resources for flood control and conservation (water supply and low-flow regulation) needs in multipurpose projects. During the flood season, it is usually essential to maintain empty space in reservoirs in anticipation of possible flood flows, whereas it is usually desired to keep the reservoir full for low-flow regulation. Toward the end of each flood season, this conflict is particularly critical because subsequent conservation benefits will depend partly on storage at that time, and it is, therefore, of particular importance to examine the project operation plans in relation to flood and low-flow expectation.

Water resources systems

If more than one water reservoir exists within a river basin or if water is diverted between basins where water resources projects exist, their overall effectiveness can be increased by coordinating the operation of each project. Such a coordination requires all the various projects to be treated as one interrelated system, considering the availability of water and the specific purposes of each project, as well as the possible interactions and trade-offs between them. A review of system operation should be undertaken as soon as a new project or a new demand is initiated that could have significant impact on existing operations.

Preliminary investigation of water management projects

Before appreciable expenditure of time and money can be justified for the role of dams and reservoirs of a water management project, a preliminary investigation is made of its feasibility, desirability, possible scope, and its possible effect on those hydrological factors which influence the environment and the efficiency of other projects, both existing and proposed. Although this investigation is based on whatever material may be available, such as fragmentary hydrological records, old maps, and reports, usually with only limited possibilities of supplementing it with new information through field surveys, aerial photographs, etc., it is carried out with great care since it is at this stage that conceptual planning decisions are often made and important aspects and consequences of the project may become apparent. If preliminary investigation indicates that the project potentialities are favorable, more detailed studies would normally be initiated.

Estimation of water demands

Estimates of water requirements for preliminary planning purposes may sometimes be made on the basis of the experience at similar existing projects in the same general area. However, estimates for final planning made on the basis of detailed studies of the present and possible future requirements for each purpose the reservoir is to serve are managed accordingly. Demands existing prior to the construction of a reservoir should be considered in the hydrological design of the project. Failure to consider these demands may cause economic losses and social

as well as legal problems in the operation and role of a reservoir. Navigation demands are usually for regulation of flow to maintain the minimum required water depth and the velocity below a safe maximum and for water volumes needed for passage through reservoir locks. In some cases, navigation depth requirements have to be met partially or entirely by dredging.

Municipal water supply

Water supply for municipalities is closely interrelated with problems of water quality. Quantitative municipal demand has usually little variation from season to season. However, a unique feature of this demand is the extremely high degree of dependability required owing to the potentially catastrophic consequences of shortages (epidemics, social disruption, etc.).

As with the municipal demand, the industrial demand is fairly constant throughout the year, and high-quality water is required in many cases.

Pollution abatement

Water quality in many rivers and reservoirs is less than desirable due to high concentration of pollutants. The situation is usually aggravated during dry periods when the ratio of effluent discharges to streamflow increases. Therefore, pollution abatement often requires low-flow augmentation to prevent the pollutants from exceeding a preset maximum level of concentration. Occasional flushing out of pollutants by surges of high flows from reservoirs is often desirable.

Nature of losses from reservoirs

Water losses, such as evaporation and seepage, occur under natural or preproject conditions and are reflected in the streamflow records used for estimating water supplies. The construction of new reservoirs and canals is often accompanied by additional evaporation and infiltration. Estimation of these losses may be based upon measurements at existing reservoirs and canals. The measured inflows, outflows, and rate of change of storage are balanced by the computed total loss rate.

In terms of water balance, seepage and infiltration do not constitute "loss" since they contribute to groundwater recharge or to discharge downstream from a structure, such as a dam, weir, navigation lock, etc. However, they constitute a "loss" as far as the primary purpose of the reservoir project is concerned, e.g., the water lost through seepage is lost for power generation or for withdrawal for water supply, etc. Thus, the term "loss" is to be understood in the water management, rather than hydrological, sense.

The depth of water evaporated annually from a reservoir surface may vary from about 400 mm in cool humid climates to more than 2,500 mm in hot arid regions. Evaporation is, therefore, an important consideration in many projects and deserves careful attention since it constitutes another demand on the circulable supply in storage.

Seepage loss from reservoirs, irrigation, and navigation canals may be appreciable if they are located in an area underlain by permeable strata. Curtailment of seepage losses can be expensive, and the technical difficulties involved can be such as to render a reservoir unfeasible.

Losses from irrigated areas

Water losses in an irrigation reservoir system may be several times greater than the water depth actually utilized by the crops. These losses are made up of excess water drained from the land surface or percolating to the groundwater, evaporation from the soil, transpiration of undesirable vegetation and seepage, and evaporation from canals. From 20% to 60% of the water diverted for irrigation may appear as return flow and contribute either to streamflow or to groundwater recharge. Chemical constituents in irrigation return flows are usually more concentrated than those in the original waters supplied and may contain new undesirable elements.

Evaporation from reservoirs

Prior to its submission by a reservoir, land loses water by evapotranspiration. For reservoir design purposes, the requirement is to estimate increased water loss from the reservoir area due to formation of a lake, that is, the difference between estimated reservoir evaporation and estimated preproject evapotranspiration from the land area. Direct measurement of evapotranspiration presents a number of still largely unsolved problems.

Multipurpose reservoirs

Most storage reservoirs serve a number of purposes, and it is usually not practicable to allocate a fixed portion of storage for each purpose. In most cases, such an allocation is restricted to emergency purposes. For example, a buffer zone is often created immediately above the dead storage zone and reserved for use in exceptional circumstances, such as flushing the downstream river section in case of some accidental contamination, emergency water supply in case of sudden health hazards, fire reserve, etc. Similarly, reservoirs may have an ungated emergency flood-control storage to prevent overtopping of the dam. However, most purposes are served from the same storage, and their requirements are accommodated by rather complex release rules for reservoir operation. Reservoir releases are often formulated in terms of rule curves indicating the rate of release as a function of the instantaneous storage and the time of the year.

The design and operation of multipurpose reservoirs requires complex analysis which is usually carried out by iterative methods involving adjustments of the rule curves and evaluation of the effects on all individual purposes, with the aim of optimizing the whole water management system involved. In such cases, the classical storage-draft-reliability relationships can only serve as the first approximation of the operating policy which is then gradually refined.

Systems of reservoirs

Procedures used in reservoir system design are similar to those described above for multipurpose projects. Because of the complex interactions among system components and between supplies and demands at various times and various locations, a direct solution is usually not feasible. Consequently, an initial design is first selected by engineering judgment and then improved by successive sequential routings.

A number of reservoirs in a basin are usually not designed as a system from the start, but the initial reservoir projects are often designed for specific purposes. As the resources of a river basin become increasingly utilized, it is necessary to study the operation of all projects as a system and to add new projects to the system from time to time. When this is done, operation of existing components might be changed, but major changes are usually difficult because of many legal, political, economic, and physical constraints. Accordingly, the level of optimization which can be reached in practice is usually rather low.

Selection of design floods

The general rule for the selection of the magnitude of the design flood is to reduce the risk of flooding (increase the design flood) inversely proportional to the extent of possible material damage. For structures involving low damage risk (such as culverts, secondary roads), the design flood may be calculated by empirical methods since the knowledge of its exact period is of relatively low importance. For structures or projects involving large potential damage but without the danger of the loss of life, design floods should be computed, wherever possible, by methods allowing an evaluation of their return periods in order that optimization methods could be used for selection of the design flood magnitude. For situations involving danger of loss of human life, the aim is to provide maximum protection and the maximum probable flood, or the standard reservoir flood is usually adopted as the design flood.

Design life of a reservoir

In the wide range of cases in which the design floods of a flood-control reservoir are selected by optimizing the relation between the expected flood damage and the cost of flood protection measures, the resulting optimum level of the calculated risk depends on the length of the period over which the performance of the reservoir is evaluated. This period is called the design life or planning horizon of the reservoir and is determined in the project planning stage on the basis of the following four time spans:

- (a) The physical life which ends when a reservoir or facility can no longer physically perform its intended function.
- (b) The economic life which ends when the incremental benefits from continued use no longer exceed the incremental cost of continued operation.

- (c) The period of analysis which is the length of time over which a reservoir may be expected to function under conditions that can be relatively accurately foreseen at the time of the analysis (operation in a distant future which is subject to a high degree of uncertainty is thus excluded from consideration).
- (d) The construction horizon which is reached when a facility is no longer expected to satisfy the future demands (functional obsolescence).

The optimum level of calculated risk and hence the design return period for each of these periods may be different, and the final selection of the design flood cannot be made without a consideration of political, social, environmental, and other nonquantifiable criteria.

Design floods for large reservoirs

The selection of design floods for spillway design for large storage reservoirs must be given special attention because of the fact that the reservoir may considerably change the flood régime both at the reservoir site and in the downstream section of the river.

Hydropower is solar energy in naturally and ideally concentrated form that can be utilized with the help of a mature and familiar technology with unsurpassed rates of efficiency and without depriving future generations in any way of raw materials or burdening them with pollutants or wastes. In many developing countries, it is the only natural energy resource. With a total annual generation of 2.1 million GWh, hydropower accounts today for 20% of electricity production and about 7% of total energy production worldwide. Even at a conservative estimate, the total exploitable hydropotential in the world amounts to at least six times as much. Very often, hydropower pays for multipurpose benefits, too. When this is taken into account, and when all environmental and social costs are internalized, hydropower compares favorably with other sources of energy.

Given the foreseeable depletion of fossil fuels, which presently are used to satisfy three quarters of primary energy requirements worldwide, plus the problem of the greenhouse effect and global warming, there is an urgent need to gradually replace them with methods of energy production which do not release CO₂, (or airborne mercury from coal-fired plants) into the atmosphere and which draw on renewable sources of energy. In the short and medium term, however, the predominant sources of renewable energy that will permit large-scale exploitation will be biomass and hydropower before new sources like the direct harnessing of the sun's energy by photovoltaics will be ready to make contributions of the same order of magnitude.

Power is generated at a rate which depends directly on the product of the discharge and a differential head of water. Hence, water demand depends on the required power output and the available head. Power plants attached to large reservoirs can use the available supplies more efficiently than run-of-river plants since they can store surplus water in the reservoir which cannot only

conserve water not needed immediately but also creates the head and thus reduces the discharges required. Run-of-river power plants can utilize only the discharge available at any specific time up to full turbine activity.

Control of floods

Flood control

Flood control is not a water use but generally a demand for a more uniform time distribution of streamflow. This can be partly achieved by various land-use management practices, such as afforestation of the basin, contour plowing, etc., but one of the most common means is the reduction of flood peaks by storing the excess water in reservoirs. There is a basic conflict between the objectives of flood control and of water conservation which has to be managed during operation of the reservoir.

Flood-control reservoirs

The volume of storage which must be provided in a reservoir will depend on the degree of flood abatement required and the flood characteristics of the stream. If flooding occurs only during certain periods of the year, the reservoir level may be drawn down before the danger of flooding begins and refilled as soon as the danger has passed. In such cases, flood abatement is achieved largely through reservoir operation schedules rather than by providing additional storage. However, in areas where a flash flood may occur almost any time during the year, storage capacity must be held in reserve at all times for temporary storage of flood waters.

Storage capacity to be held in reserve exclusively for flood control purposes can be provided either in on-stream or in off-stream reservoirs, while multipurpose storage is usually provided in on-stream reservoirs (An on-stream reservoir is a reservoir behind a dam constructed across a river, whereas an off-stream reservoir is situated aside from a river and is connected with it by canals, sills, or otherwise).

Regional detention storage

Full control over the flood-detention storage of a reservoir provides for the highest efficiency of the flood mitigation effect of this storage because it makes it possible to start storing water only after the highest permissible flow (also called the nondamaging flow) has been reached downstream from the reservoir. Only that portion of flood water which is apt to cause damage is stored.

The control over storage is achieved by regulation of a gated outlet in the case of an on-stream reservoir and of gated intake and outlet in the case of an off-stream reservoir. In an on-stream reservoir, full control is achieved only: (a) if the outlet has a capacity sufficient to release the nondamaging flow when the reservoir storage is at its minimum and (b) if the release of water from the detention storage can be fully regulated.

In an off-stream reservoir, full control is achieved only: (a) if the intake has a capacity sufficient to prevent the rise of flow in the downstream section of the river above the

nondamaging flow and (b) if the release of the detained water can be regulated.

It may also be mentioned that the design flood for the selection of the flood-detention storage capacity of a reservoir need not be the same as the design flood used for the design of its spillway since the safety requirements for the dam itself are usually different from the normal flood protection requirements downstream from the reservoir.

Unregulated on-stream detention storage

The storage above a fixed spillway crest of an on-stream reservoir is generally regarded as unregulated for design purposes, although it may be partially regulated by release through gated bottom outlets and turbines. However, for the design of the unregulated detention storage, either these releases are considered constant (often only a fraction of the actual outlet capacity) during the passage of a flood, or the outlets are considered closed. The former condition is usually adopted for the assessment of the normal downstream flood-control effects of the reservoir, while the latter condition is applied for the assessment of the dam safety.

The unregulated detention storage plays an important role in the safety of a dam against overtopping. Its design is interlinked with the design of the dam spillway and must be based on the same design flood as the spillway itself. Safety considerations in spillway design require that the reservoir be regarded as filled up to the spillway crest at the beginning of the design flood.

Unregulated off-stream detention storage

This type of storage arises in off-stream reservoirs (sometimes called "polders" because of structural resemblance to real polders) constructed by enclosing a part of a flood plain by a dyke whose crest at the upstream end is lowered to form a sill, i.e., an intake into the enclosure. When the river stage at the upstream end rises above the sill crest, the polder starts filling by overflow over the sill, thereby reducing the flow in the river. The fact that the river bypasses the reservoir makes the unregulated off-stream storage more efficient than unregulated on-stream storage since the unnecessary filling starts later.

Operation considerations for design purposes

Flood-detention storage is most frequently provided in multipurpose on-stream reservoirs with gated outlets of a capacity sufficient to provide a high degree of control of the reservoir storage. These reservoirs always have some ungated flood-detention storage (either because the spillway has no gates or, if it has, some storage above the crest of the gates must be provided to allow an emergency overflow of the gates which may become stuck in the closed position) and, in many cases, they also have a designated part of the gated storage reserved for flood detention. In addition, storage designated for other uses may occasionally be used for flood control purposes.

This diversity offers great flexibility and makes the flood reduction strongly dependent on the mode of reservoir operation. It is, therefore, necessary in such cases to analyze many different operation modes during the early stages of design since the results may affect the selection of the design variables for the project.

Time interval between successive floods

The use of storage reservoirs to reduce floods raises the question of a possible occurrence of two or more floods in close succession and hence the possibility that the detention storage filled by one flood may not be emptied before the arrival of the next flood. The problem is essentially one of frequency distribution of the times between flood events (volumes, peaks) of specified magnitudes and can be solved by frequency analysis of historical streamflow records, synoptic weather patterns, or synthetic streamflow records derived from precipitation records via deterministic models. However, care must be taken in extrapolating the frequency curves of the between-flood intervals in order to prevent the violation of physical constraints. Thus, for instance, where major floods are caused by snowmelt then, once the snow has melted and the corresponding flood has passed, the time to the next flood must be longer than the whole period of above-freezing temperatures. If this period is a number of months, it would be meaningless to extrapolate the frequency curve down to time intervals of a few weeks or days. Similarly, even if frequent curves derived from historical records for two areas – one of which was subject to tropical cyclones and the other, not – were identical, the likelihood of two major storms occurring only a few days apart would be much higher in the cyclone-affected area than in the other one.

Flood control has always been a particularly significant motive for dam construction and frequently its primary purpose. It will continue to be so as long as about 40% of all fatalities from natural catastrophes worldwide are caused by flooding, amounting to a frightening total of nearly 100,000 per year. Compared with the main requirements of irrigation, domestic and industrial water supply, energy production, and flood control, the other purposes and benefits of dams, such as navigation, fisheries and tourism, improvements to the infrastructure, job creation, and on-site training, are of generally minor importance but must nevertheless not be disregarded or underrated.

In spite of this, there has been hint of a change in the United States, and an environmental lobby has existed there since the 1980s, who are generally opposed to further dam building in the USA; “much of our water has been developed; we have developed thousands of huge lakes, some more than a hundred miles long, flooding an area the size of Vermont and New Hampshire combined; we have made more than two and a half million smaller lakes and ponds. We have turned dangerous rivers into staircases for ships and transformed the ancient roar of rapids into the hum of electricity; the flow of deep,

cold water from the bottom of reservoirs is often so poor in oxygen that all aquatic life downstream is affected.” (*National Geographic*)

‘Flow gently sweet Afton among thy green braes
‘We’ll be damming thee up in a couple o’ days’

Clearly, a difficult problem on water resources management may arise in such circumstances, which has to be resolved.

Future upstream development effects

The design of a flood-control reservoir is based upon analyses of floods which occurred in the past, although the reservoir is to control future floods. The growth of population and the increase in the standard of living result in an intensified land development. Forests are transformed into agricultural lands, drainage of agricultural lands is improved, etc. The change from manual labor to mechanization in agriculture, the extension and intensification of urbanization, etc., often contribute to increased volumes and discharges of surface runoff and, frequently, also of sediment transport. On the other hand, application of sound soil conservation practices contributes to their decrease. Evaluation of the hydrological effects of land development is difficult, yet the hydrologist should be aware of its effects of increasing flood risk.

Estimation of maximum reservoir levels

Reservoirs are designed for water levels somewhat higher than those which may be attained during the maximum flood as a safety measure against wind setup, wave action, wave run-up, and periodic undulations of the water surfaces (seiches). This “freeboard,” or allowance for additional rises in water level, cannot be considered as adding to the useable storage, although it may provide a factor of safety against floods greater than the maximum design flood. Greater freeboard is usually provided for earth dams, particularly in areas subject to earthquake effects or severe frost action.

Wind setup

The result of wind blowing over the water surface of a reservoir is to pile up water at the leeward end of the reservoir and to lower the water level at the windward end. This wind setup and setdown is more pronounced in shallow than in deep water.

Winds blowing across reservoirs also generate waves that eventually reach and run up on lake shores and the upstream face of dams. Adequate freeboard to prevent overtopping of a dam by waves is required. The run-up of the waves is a function of the wave height, wave length, and the slope of the embankment.

Reservoir design must normally be based on wind data obtained at land stations with an overland fetch to the recording site. One of the most difficult meteorological problems in estimate wave heights is determining the wind field over the lake from land-based wind observations.

The ratio of wind speed over land to wind speed over the lake depends on the stability of the air mass over the lake, which depends on the temperature difference between the water surface and the overlying air. It also depends on the "roughness" of the topography at the land-based measuring station.

Waves are critical only when a reservoir is near full storage level. Thus, only winds which can occur during the season(s) of high water levels need to be considered. The height above the still water level to which the water will rise as a result of wave action is termed "the run-up." This elevation depends on the embankment slope and wave steepness.

Periodic undulations of water surface

In restricted bodies of water, such as reservoirs, periodic water surface undulations may be caused by variations in the rate of inflow or outflow, wind action, sudden changes in atmospheric pressure, or by earth temperature. Depending on the physiographical characteristics of the reservoir, these waves may be reflected either from shorelines or at places where abrupt changes occur in the reservoir width or depth. In a long, narrow body of water, a series of waves may be set up with several nodes and antinodes.

There is no method available for computing the height of waves due to such causes as a sudden change in atmospheric pressure or earth tremors. Total freeboard allowance for these phenomena may vary from several centimeters up to about 1 m, depending on the size and importance of the reservoir.

Sedimentation

When approaching its mouth, the flow velocity of a river decreases and with it, the ability to carry sediment (Coarse sediments aggrade first, interfere with the channel conveyance, and may cause additional river meanders and distributaries). The area of the flowing water expands, the depth decreases, the velocity is reduced, and eventually, even fine sediments begin to aggrade. As a result, deltas may be formed in the upper portion of reservoirs. The deposited material may later be taken to lower portions by hydraulic processes within the water body.

Sediments are deposited in accordance with their settling velocity. A relationship between the grain size and the settling velocity may be developed. A considerable concentration of suspended sediments may remain in the water for several days after their arrival into a reservoir, which may interfere with the use of the stored water for certain purposes, such as water supply or recreation.

It should be emphasized that not all of the sediment formed aggrades in a reservoir. A large portion of it remains in the upper zones of the watershed, some is deposited upstream from reservoirs, and some is carried downstream by the released water. The sediment trapping efficiency in a reservoir depends upon the hydraulic

properties of the reservoir, nature of the sediment, and the hydraulic properties of the outlet. The density of newly deposited sediments is relatively low but increases with the passage of time. The organic component in the sediment may undergo change which may reduce its volume and enhance biochemical processes in the stored water.

Sediment control measures fall into two broad categories: (a) land treatment measures for watershed protection and (b) structural measures. The aim of land treatment measures is to reduce erosion in the watershed and thereby the rate of sediment formation by improving the protective cover on the soil surface, reducing surface runoff, and increasing infiltration rates.

The deposition of sediments reduces the storage capacity of a reservoir and thereby the reservoir's ability to perform its function. Most reservoirs have a certain part of their storage capacity designated for sediment deposition in order to prevent the reduction of the active storage. However, it often happens that this storage is inadequate. The flood-detention storage is usually significantly affected since it occupies the upstream part of the reservoir where sedimentation often occurs due to both bank erosion (along the whole circumference) and river-sediment deposition (upstream part of reservoir). Thus, it is generally the case that the flood-reduction efficiency of a reservoir decreases with time. This should be considered in long-term flood protection planning in order that alternative measures can be developed in time.

Thermal stratification

Thermal stratification is a result of natural factors. However, thermal pollution may be a contributing element. Thermal stratification corresponds, particularly in nutrient-rich lakes, to dissolved oxygen stratification and frequently to the stratification of other dissolved substances.

The epilimnion, i.e., the upper layer of water which is warmer in summer, generally has higher water quality. In the upper layer, one may expect reduction in silicate content following an increase in diatoms and decreased hardness due to inflow of direct precipitation water that did not have prior contact with the soil or an opportunity for biogenic extraction of calcium.

The hypolimnion, i.e., the deeper layer of water which is colder in summer, has a reduced dissolved oxygen concentration. One may expect an accumulation of various substances in this layer due to deposition on the bottom and absorption by sediment and in living organisms. Anaerobic decomposition of algae and other organisms usually occurs in the hypolimnion. One may expect the hypolimnion to show trends of increasing concentration of ammonia and hydrogen sulfide, reduction in nitrate and sulfate concentration, accumulation of sediment and occasionally of heavy metals, and periodic increases in iron, manganese, and phosphate concentration. During the turnover, caused by the seasonal cooling

of the surface layer of the lake, a convective circulation takes place, which results in mixing and a uniform temperature.

In addition to the effects listed above, one may expect that in large lakes and reservoirs, organic matter is biodegraded to a large extent due to long residence time, that variations in water quality are dampened out for the same reason, and that algae trigger the formation of chelating substances and halocarbons (Figure 1).

Effects of reservoirs on water quality in streams and rivers

By raising the water level, a dam – and to a lesser extent, a weir – has usually the following effects on water quality in the upstream reach of the river:

- Intensification of self-purification processes due to increased residence time in the reach, better sedimentation of suspended solids resulting in increased solar radiation, and in changes in the sediment characteristics of the river bed.
- This in turn leads to a rise in phytoplankton production, greater oxygen consumption, and increased day–night fluctuations in oxygen, pH value, and CO₂.

Fish migration is usually disturbed both by the physical barrier and by changes in water quality. Changes in bank vegetation, which are governed by local topography, climate, and water level variation, may also affect water quality. In cold climates, dams – and to a lesser extent, weirs – create favorable conditions for an extended duration of the ice cover in the upstream reach. This leads to a decreased reaeration. Further effects in the case of large storage volumes may result from thermal

stratification. Increased pollution loads retained in the upstream reach may lead to eutrophication or to anaerobic conditions.

The effects of a dam or weir on water quality in the downstream reach depend on the upstream storage volume, dam design and operation, and other factors. The most important effects are the following:

- Reduction in suspended solid load pollution load and turbidity.
- Changes in the chemical characteristics of the water, often a lower concentration of dissolved oxygen and nitrates, and increases in phosphate, CO₂ and H₂S, the latter particularly when anaerobic conditions prevail upstream.
- Decrease in the summer water temperature and increase in the winter temperature.
- Reduction of the day–night temperature fluctuation to which the river flora and fauna are adapted.

Flow reduction and augmentation

In addition to the flow-regulation effects of dams, many water resource projects involve flow reduction by abstractions for various water supply purposes or augmentation due to inputs of water coming from sources outside the basin.

When the abstracted water undergoes a treatment and the resulting sludge and residues are dumped in the donor river, or when the abstracted water is obtained from the less polluted turbid portions of the river cross-section, the abstraction effects are equivalent to a reduction in flow and to a pollution input. The disposal of sludge and residues is usually subject to control by legal requirements for the quality of effluents.

The effects of flow augmentation depend mainly on the quality of the additional water as compared to that of the river water. An addition of water of poorer quality is equivalent to a pollution input.

Water quality in large lakes and reservoirs

Water quality in large lakes and reservoirs can be improved or worsened by water resource projects, depending upon the nature and operation régime of the project. A water resource project involving a withdrawal of water of a better-than-average quality (e.g., from the epilimnion) will generally worsen the water quality in the lake. The same is true when water of a poorer-than-average quality is introduced into the lake or reservoir.

Water quality in a large reservoir depends to a large extent upon the characteristics of the underlying terrain before flooding and upon the treatment applied to it. If the future reservoir bottom is covered by soils with rich organic (humus) content, the latter is leached after the reservoir is filled, and accelerated eutrophication may result. This may be avoided by removal of vegetation and soil prior to flooding which usually is a costly operation.

Dams and Reservoirs, Role, Figure 1 Representative profile showing summer stratification in a large storage reservoir, with a high dam (World Meteorological Organization, 1983).

Water quality changes due to pollution relate to physical, chemical, and biological characteristics of the body of water. The effects of pollution on lakes are generally different from those on rivers because of the differences in the hydraulic, hydrological, and ecological conditions. In addition, lakes are liable to present a significant variation in water quality, whereas rivers are generally more homogeneous, although significant quality variation may sometimes occur in rivers downstream of significant inflow points.

Eutrophication

One of the most common forms of pollution is related to excessive concentrations of nutrients originating either in urban waste waters or in rural runoff. This usually results in excessive development of algae populations – particularly in areas with low water velocity – and in significant reduction or disappearance of a number of plant and animal species. This process is known as eutrophication.

Eutrophication is, in fact, a natural process marking the maturing and aging of lakes. However, under conditions not involving man's activity, this process takes hundreds or thousands of years, depending upon lake size, hydrological conditions, and land cover in the basin. Civilization, particularly in its current industrialized form, is responsible for accelerated eutrophication in a large number of lakes all over the world.

The problem of eutrophication and its causative factors is one of the current major water quality problems. Although much research has been devoted to it, it is not yet possible to explain quantitatively the process of nutrient enrichment composition of certain industrial products (e.g., elimination of phosphorus compounds from detergents), artificial cooling of industrial wastewaters, etc.

If pollution originates in the matter washed away by runoff from the surface of a river basin (e.g., pesticides and herbicides, fertilizers, urban uncontrolled waste), pollution abatement can be obtained only by changing the practices that lead to uncontrolled spreading of the pollutants in the river catchment and measures to reduce runoff and soil erosion.

Significant pollution is generated by soil erosion. Prevention in this field requires adequate forestry management and construction and farming practices. Finally, pollution from leachate resulting from garbage dumps is locally very significant. By appropriate location and design of such dumps, this can be avoided.

Corrective measures

Reducing pollution in water bodies after pollutants have reached them is generally difficult and costly. In most cases, it is possible only to treat the water abstracted from the water body for various purposes (e.g., domestic or industrial water supply). However, in special circumstances, some remedial work can be done for the whole water body. Such remedial work consists, in the case of rivers, mainly in artificial

reaeration (oxygenation), or mixing and dredging of settled pollutants, and, in the case of lakes and reservoirs, of the following measures:

- Emptying the lake regularly during the period between late fall and early spring to expose the organic matter directly to air and permit the aerobic decomposition of organic matter.
- Dredging the bottom of the lake in the areas which contain most of the organic and polluting matter.
- Forced reaeration by compressed air in the deoxygenated layers and “harvesting” and disposing of organic matter produced in the form of algal bloom, undesirable fish, etc.

The first two measures have a negative side effect, the killing of fish. Remarkable work in the last three measures has been carried out in Sweden.

DAMS, CLASSIFICATION

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

Demand for water is increasing worldwide at twice the population growth which itself is growing at the rate of 90 million a year.

Annual precipitation is estimated at some 110,000 km³, of which 70,000 km³ evaporates or infiltrates. Of the remainder, 40,000 km³ runs into the oceans, 14,000 km³ into rivers, and 26,000 km³ below ground as groundwater.

Seasonal variations of both rainfall and runoff can be significant, and freshwater resources are unevenly distributed and in some cases deserts which rarely see rain and humid areas where floods occur practically every year.

It is clear, therefore, that storage is required to satisfy demand even in regions with abundant rainfall. If not,

the runoff of whole regions may be lost to the oceans and regional demand may not be met.

The present world storage capacity is about 6,000 km³. It follows that in order to satisfy worldwide demand, the necessary increase in storage may only be met by dams.

Purposes of dams generally include:

- Irrigation 48% of all dams
- Hydroelectric power 20% worldwide: in Europe 40%
- Water supply 15%
- Flood control 8%
- Recreation 4%
- Inland navigation and fish farming

Dam construction

Types of dam construction are:

- Earth 64%
- Gravity 19%
- Rockfill 8%

- Buttress 1.4%
- Barrage 0.8%
- Multiple arch 0.5%

Generally, dams less than 30 m high represent about 62% of all dams, dams less than 59 m account for 90% of the total, and only 2% are more than 100 m high.

Records of the world's dams are kept by the International Commission on Large Dams (ICOLD) in Paris. In 1950, there were only 5,196 dams in service in the world. Today there are of the order of some 36,000.

The given tables classify the number of dams by country (Table 1), the highest dams of the world (Table 2), and the dams with height over 150 m (Table 3).

DAMS, FLOOD PROTECTION, AND RISK

Klas Cederwall

Department of Land and Water Resources Engineering,
Royal Institute of Technology, Stockholm, Sweden

The vital role of water

Our Earth has an abundance of water resources which is a fundamental factor in creating biological life and hence also human societies on this planet. On the other hand extreme hydrological events have always been a significant threat to human lives. Even the Bible tells us about the horror brought upon the ancient societies by the uncertainties of hydrology. We have always known that floods and droughts demanded some level of preparedness and coping strategies from society. Protection using levees, different land use depending on the season, and for instance floating houses all represent forms of coping with climatic variability related to flood events. Droughts were usually more problematic often leading to large-scale migration in order to cope with its harsh consequences. But water is more fundamental in our life than this. Ending poverty is often said to begin with water, clean water. Poor health, hunger, and lack of education are symptoms of the full scale of the true problem – including basic issues of availability of water of sufficient good quality.

Dams in the historical perspective

Dams and reservoirs have been used for thousands of years mostly as embankment dams in order to facilitate water storage primarily for water supply and irrigation and as water protection structures. At the same time hydrological variations in the river flows and water levels made it possible to irrigate flood plains. Water-dependant cultures and human civilizations developed in certain regions – Egypt, Mesopotamia, China, and India – where large rivers not only provided water resources but also due to the erosion and sediment transport capacity they

assured fertile soil deposits along the floodplains as a basis for agriculture. The oldest known earth dam was constructed as early as 3200 BC near the city Java in Jordan providing water supply to the city.

Many of these dams were built to protect populated areas and farmlands against devastating flooding events. The dams, often long systems of low embankment dams such as levees, dikes, and sometimes concrete or masonry structures as seawalls, often have to be combined with a drainage system in the protected area and pumping stations to handle local rain and water leaking into the protected area to maintain water balance in particularly lowland areas.

Dam safety

In all studies of water resources projects including water storage dams for water resources management and hence also flood and drought mitigation, the dam safety issue has to be considered. Water regulation and dam safety are closely coupled in a complicated way. An effective and safe use of water in the river system is normally based on water regulation by means of dams. A dam failure in the river system during an extreme high flow situation, particularly far upstream in the river, may then result in an additional dam break flood wave superimposed on the natural hydrological flood wave together propagating downstream, a severe situation that can cause other dams to fail further down in the system as a “domino effect.”

The dam owner has a responsibility for the overall performance of the dam. Dam safety is normally a strict responsibility in the sense that whatever the cause is of a dam failure and the following release of large volumes of reservoir water, the responsibility for the consequences to society has to be taken by the dam owner. This important responsibility cannot be delegated to someone further down in the organization. Different tasks related to maintaining a safe and effective dam performance can be directed to appropriate persons and levels in the organization that operates the dam and reservoir facilities. But the overall responsibility for the dam safety is always that of the dam owner.

Special roles are given to national authorities for the overall assessment of dam safety regulations as well as for regular supervision, inspection, and control of the dam safety status on a project level. Dams are classified according to risk perspective. Risk is then defined as the combined effect of probability for a negative event and its consequences. International and national associations collaborate to continuously update theoretical and empirical findings related to dam safety. A dam safety program should be developed and managed for every dam that can cause significant damage. The management of large dams and reservoir systems can benefit from being assessed by international dam expert teams as a means of an effective exchange of strategic dam management knowledge. A very challenging situation is dam construction in seismic areas. The most severe catastrophic events appear when a dam fails emptying the reservoir water

volume due to a combination of extreme high flows in the river system and an earthquake!

Perhaps the most important aspect of dam safety is a scientifically embedded and well-balanced knowledge base. Knowledge comprises both theory and practice. Dam design and construction, in all its elements and applications, in which climate issues and environmental impacts are key concepts, must be based on a scientifically sound knowledge base and make use of all the experience that may be documented in the form of best management practice.

Environmental and social impacts of large dams

The availability and use of water in water-scarce regions can be improved by means of water regulation dams and reservoirs for water storage. But particularly large dams can cause social and environmental damage if not properly designed and operated. Let us take just one example. The Narmada Valley Development Project in north-western India in the Narmada river system is a huge project with a number of large dams. The planning procedure as well as the way of mitigating negative social and environmental effects have been strongly criticized, particularly related to the two large dams Sardar Sarovar and Maheshwar. The Narmada Valley Development Project has been accused of violating several of the World Commission of Dams (WCD) guidelines with respect to the requirements set by the Commission particularly as related to a fair process for compensating project-affected people and a thorough analysis of alternatives as well as the absolute necessity of "Prior Informed Consent." WCD formulated these basic and important guiding principles in their report from 2000, "Dams and development – A new framework for decision making."

Integrated water resource and risk management

Sustainable water resources management emphasizes the need for an integrated and systems-oriented approach to balance different sector interests in the effective use of water resources as well as the minimizing of different risk perspectives particularly related to flooding and drought phenomena. Strategic water management then has to be based on multi-objective utilization of dams and reservoirs for water regulation of lakes and river systems.

Water resources management has a basic component of planning for utilizing available resources and hence also for effective preparedness of successful risk mitigation. The management strategies have two different elements: structural and nonstructural measures. Information, mainly with real time prediction systems, and public participation to increase awareness also improving the decision process, are essential parts of the risk mitigation. Dam design criteria and maintenance procedures also need to be continuously assessed and upgraded.

Systems engineering can be defined as an interdisciplinary field of engineering that focuses on how complex engineering projects should be designed and managed, that is, the application of engineering and systems analysis

to solutions of normally quite complex societal problems. The systematic matching of parts in the system encompasses subsystems, components, and modules that interact to produce specific objectives or results.

Applying risk management in this form, a number of basic perspectives have to be considered:

- Identification of risks and uncertainties and how they can be analyzed and evaluated
- Measures that have to be taken in order to reduce the risks to acceptable levels
- Development of systems that can be applied to provide a reliable understanding and control of various risks

Environmental impact assessment (EIA)

In the EU and also in other countries water directives require that an environmental impact assessment (EIA) is developed in the case of major infrastructure projects such as for water regulation dams. The purpose is to get an overall evaluation of the environmental as well as social impacts of the project before it is finally accepted. This assessment will be effective only as an integral part of an open and independent general discussion in society. A focus is on the planning process to actively involve "project-affected people." This is particularly important for projects with large dams and reservoirs that will cause resettlement of people due to inundation of water in the created water reservoir.

International collaboration

Many countries are dependent on water resources that originate upstream in other countries and therefore also controlled by these upstream countries. Actually more than 50% of the surface water resources in the world are shared by two or more countries. This can lead to political problems but also be a reason for international collaboration on the effective use of available water resources including more effective flood risk management. Another example is management of water scarcity when water-rich regions/countries can supply water-scarce regions/countries through water transfer systems of different types.

Floods and flood mitigation

Floods in rivers appear normally due to intensive precipitation as accumulated, superimposed flow components from different subcatchments in the drainage system. In steep river systems this may produce flash floods that are very concentrated and intensive local flow situations. A particular flooding problem follows a dam break when the reservoir water is emptied directly into the river drainage system.

Human societies have been interested in the use of flood plains since early times. Several benefits would arise from this utilization since in the flood plains the soil is fertile and the agricultural yield higher. Access to the river and river transportation was also easier. To reduce the problems of repeated periodic flooding it was necessary to develop structural alternatives to control extreme high

water levels. Levees and dikes are protecting land from flooding without essentially changing a flood wave that propagates downstream in the river. Flood mitigation schemes, however, should reduce the peak of the flood by the possible detention effects that can be achieved using the storage capacity that the reservoirs of these kinds of dam structures provide. Such retention of, for instance, seasonal high river runoff from a combination of precipitation and snowmelt in dam reservoirs requires very large storage volumes to significantly affect the runoff characteristics, particularly in the middle and lower parts of the river basin. A severe problem is sediment transport in the river system that can cause siltation of reservoirs and river branches and delta formations contributing to flooding. The huge High Aswan Dam in the Nile River has a water storage volume of the order of 150 km^3 whereas the annual sediment volume “trapped” in the reservoir is on the average about 1 km^3 which means that the practical service life of the High Aswan Dam project may be reduced to between 100 and 150 years due to sediment siltation problems.

Damages to economic assets resulting from natural disasters have increased significantly in the past say 20 years. Climate change will lead to intensified exposure to extreme weather conditions. Natural causes of the floods are related to rainfall intensity and its distribution, soil type and coverage, and several geomorphologic aspects of the watershed. Man-induced conditions may increase the risk of flooding, mainly deforestation, urbanization, unsustainable agricultural practices, and channelization/drainage and shifting of runoff pathways.

An important principle in more active flood mitigation is to spread apart in time accumulating flood components in different merging branches of a river system which will reduce the peak flow and associated water levels downstream and hence the risk for flooding. The situation when flow components accumulate in a branched river system and related problems of risks for flooding downstream is illustrated in [Figure 1](#). The principle of detention and flow peak reduction when a flow component following for instance a local rain storm is passing a natural, unregulated lake is demonstrated in [Figure 2](#).

Flow peak retention can be achieved also by creating more temporary storage capacity in the river system by, for instance, diverting water from the river into shallow flood mitigation reservoirs that can be localized in the landscape – “ecoflooding.” These detention storages must be effectively controlled hydraulically so that the temporarily stored water can be diverted back into the main river as soon as the flow capacity downstream allows that.

Multipurpose water management strategies that integrate flood control with hydropower production, water supply, irrigation, navigation, and environmental protection are of particular interest for many countries. This can also take the form of integrating dams, reservoirs, and detention basins for water diversion into the landscape and environment in order to reestablish a close and effective relationship between the river runoff system and local

Dams, Flood Protection, and Risk, Figure 1 Flow components accumulating downstream in a branched river system.

Dams, Flood Protection, and Risk, Figure 2 Natural retention and flow peak reduction following a flood wave passing through an unregulated lake.

communities to promote a more sustainable societal development. Multipurpose retarding basins in, for instance, Japan have been designed in addition to flood protection also to serve as centers of recreation including sport facilities and natural park areas.

Urban storm water management

In urban areas storm water management has to handle significant surface runoff since natural infiltration of precipitation is reduced due to the amount of impermeable surfaces that are typically found in urban environments.

This is as a result of pavement of streets and storm water arrangements that does not normally allow for natural infiltration processes. Storm water is often quite polluted and has to be treated before it is disposed to natural receiving water environments. To deal with storm water management in urbanized areas we have to develop what is often called “urban hydrology” providing more statistical and local information on intensive rains and modeling capacity for this type of rapid runoff processes.

Coastal protection systems

There are several large flood and coastal protection systems developed around the world. In the Netherlands more than one third of the land is located below sea level. During the devastating North Sea Flood of 1953, the levees and dikes that should provide protection against flooding failed at several critical points in the Netherlands killing almost 2,000 people and many more had to be evacuated. The Delta Works Project was implemented to prevent the recurrence of similar disasters. The Dutch Delta Commission is now responsible for the long-term strategic planning and implementation of the coastal defense considering climate change and alarming perspectives of significant long-term seawater level rise.

There are similarly a number of very severe floods on the *River Thames*. One of the worst floods on the nontidal, inner part of the river Thames occurred in 1894 following exceptionally heavy rains. In 1953, the combination of a north westerly storm and high tide caused a very high spring tide and the sea level to rise almost 3 m above normal spring tide level along the coast and the Thames Estuary with severe flooding as a result. This disaster initiated the construction of the Thames Barrier System.

Venice has a unique history and it is an important touristic center as one of the most beautiful water cities in the world. But Venice also has serious problems with flooding. Coastal flooding of the city with severe inundations of more than 90% of the City is becoming more frequent. Additionally to the inconveniences this is causing the City, intrusion of saltwater into the foundations of the buildings of Venice is a major problem threatening the cultural treasures of the City. To reduce the hazards to the City a flood warning system has been developed based on statistical and hydrodynamic modeling which will be a vital component also in the efficient operation of a storm surge barrier covering the three existing inlets to the lagoon of Venice.

St Petersburg, a beautiful water city, is with its five million inhabitants the largest City in the Baltic Sea Region. Since the very beginning St Petersburg had a variety of problems due to its localization in a marshy lowland area, particularly severe and relatively frequent flooding events caused by high flow situations in the river Neva, and simultaneously high water levels in the Finnish Bay. Another complicating factor is significant ice and snow jamming in spring time when the river is flowing through the complicated system of canals and natural river branches in St Petersburg out into the Finnish Bay.

The 25 km long flood control dam system at the old fortress Kronstadt is a huge project for protecting St Petersburg from high water levels in the Finnish Bay. It is soon to be completed, now with a more pronounced focus also on environmental and water quality aspects.

Stockholm is one of the most beautiful water cities in the Baltic Sea Region. The Lake Mälaren has its outflow to the Baltic Sea through the central parts of Stockholm by two short outflow branches embracing the Old City of Stockholm and ending into the inner part of the Stockholm Archipelago. Stockholm and Lake Mälaren have also significant flooding problems at the same time as the lake is an extremely important regional freshwater resource that has to be protected from saltwater intrusion. Sea level rise will ultimately reduce the capacity to handle the discharge of Lake Mälaren to the Baltic Sea making also the Subway system of Stockholm more vulnerable to the risk of water entering the subway from Lake Mälaren. Water has hence become a dynamic, strategic, and multidimensional component in the regional planning in the Stockholm – Mälaren region.

New Orleans is located at the delta formed by the huge Mississippi river system. The delta is instable since the marshy land area is subsiding and therefore depending on a steady sediment supply from the river. Tropical cyclones develop regularly in the Gulf of Mexico. Hurricane Katrina, August 23–30, 2005, had Category 5 with max wind speed 95 m/s when hitting the New Orleans area. This was the most devastating natural disaster in the history of the United States with almost 2,000 people that lost their lives in the storm and subsequent floods and material damages well in excess of \$100 billion. Approximately 80% of the New Orleans Metropolitan area was flooded with water depths exceeding 5 m in some areas. The consequences were a major breakdown in the social structure of New Orleans with hundreds of thousands displaced of which many have still not returned.

What went wrong? Primarily the following:

- The New Orleans *hurricane protection system* did not perform as a system!
- The *maintained design risk* for a 100-year storm event was inadequate.
- Flooding occurred when dikes/levees were overtopped but 4 of the 50 dike breakthroughs happened *before water levels reached the design levels*.
- *Pump stations were inoperable* due to lack of power supply and being not accessible for operators.
- The public did not appreciate the risk!

Not only Thailand but also Japan suffers regularly from major catastrophes caused by tsunamis. A tsunami is a well-known phenomenon appearing as a very long ocean wave generated by earthquakes or slides at the bottom of the ocean. The wave height is moderate in deep water but may pile up to a considerable height when reaching shallow coastal waters and it is therefore a major challenge to coastal protection systems in areas threatened by tsunamis. Effective tsunami warning systems in sensitive

coastal areas are absolutely necessary since these terrible waves propagate quickly to the coast very soon after initiation.

Extreme events of droughts

Long periods of drought often lead to population migration. Several areas in the world today are under the threat of severe drought, both in the developed and developing world, such as parts of Australia, East Africa, India, China, Pakistan, Nepal, Myanmar, and many other countries. Periods of drought can cause significant environmental, agricultural, health, economic, and social losses. Rainfall variability at a timescale from years to days is as much a characteristic of climate as the total amounts recorded. Agricultural drought occurs when water supply is insufficient to cover crop or livestock water requirements. Much more than the occasional widespread and severe climatological droughts which catch the attention of the media, it is this “invisible” agricultural drought which prevents farmers at the subsistence level from achieving regular and high yields. Such drought is caused by environmental degradation as much as by climate. Drought losses are not as easily accountable as flood losses, mainly due to their length of occurrence, but they also represent a heavy burden to society.

In April 2008, a combination of drought, failed harvests, and the continued rise in global food prices left millions of people facing hunger in Ethiopia, Kenya, Somalia, and Somaliland. In Ethiopia, the government estimated that close to five million people were in need of emergency food aid. Areas which normally get two rainy seasons a year have had inadequate rain for more than 12 months. Crops failed, livestock have been dying. In northern Kenya, Tangelbei division and the larger part of Baringo district had serious food and water shortage, causing the deaths of vital livestock. Food security in this area was deteriorating and further complicated by rising food prices.

Climate change and sea level rise adaptation

Preparing for the accelerating increase in sea level that will take place in the future as a result of global warming and glacial ice sheet melting is very much needed. The reports from the Intergovernmental Panel on Climate Change (IPCC) are comprehensive documents summarizing the impact of global warming on the planet. But they are not without deficiencies, and one of the most notable was the analysis of future sea level rise contained in the Panel report from 2007. Given the complexities of forecasting how much the melting of the Greenland and West Antarctic ice sheets will contribute to increases in global sea level, the IPCC did not include these huge ice masses in their calculations, ignoring what is likely to be the most important source of sea level rise in the twenty-first century.

The serious threat posed by rising sea levels is obvious, especially since there is evidence from the past 2 years of the accelerated melting of the Greenland and West Antarctic ice sheets. The consequences of a major sea level rise are

massive. Coastal erosion and land retreat will increase at many locations. Agriculture will be disrupted, water supplies will be degraded by saltwater intrusion, storms and coastal floods will reach further inland, and millions of environmental refugees will be created – 15 million people live at or below 3 ft. sea elevation in Bangladesh, for example. Governments, especially those in the developing world, will have additional severe problems.

The most vulnerable of all coastal environments are deltas of major rivers, including the Mekong, Irrawaddy, Niger, Ganges–Brahmaputra, Nile, and Mississippi. Here, land subsidence will combine with global sea level rise to create very high rates of what is known as “local, relative sea level rise.” Rising sea levels may displace a vast majority of people in these delta regions. The city of New Orleans can probably be protected into the next century, but only at great expense and with little guarantee that future storms like hurricane Katrina will not inundate the city again. The world’s major coastal cities undoubtedly receive most of the attention as sea level rise threatens infrastructure. Miami is the most endangered city in the world measured by the value of property that would be threatened already by a 3-ft. sea level rise.

Concluding remarks

Dams and reservoirs in river systems provide the fundamental basis for more effective use of water resources. A special emphasis is in this context on the development of multipurpose water regulation strategies for well-coordinated use of the different water storage reservoirs in the system to properly balance a variety of possible interests in water resources management. Hence, the variability of the river runoff components in the catchment can be handled by using the storage capacities that the dam reservoirs provide for more stable water supply and irrigation needs and also for very often quite important hydropower production.

This is particularly essential for managing risk problems in the river system related to both flooding and drought situations. However no damping can be achieved in the river system locally and downstream in an extreme high flow situation if the reservoir storage is full at that time – there is no free or “live” volume in the reservoir for flow detention and no water can be drawn from the reservoir if the reservoir is empty in a similar drought situation. The degree of water regulation seen, for example, as a ratio of available storage capacity upstream a certain point in the river system relative to the corresponding value of the mean annual runoff should for hydrological conditions applicable to for instance northern Europe be of the order of 0.3 to enable an effective use of water all year around. This regulation degree will not be sufficient in most subtropical and tropical climates. Additionally and most important, more dynamic water regulation strategies based on both short and long-term meteorological and hydrological weather and runoff predictions are required for implementing effective water resources management systems.

The complexity of applying systems-oriented water resources and risk management for river systems is obvious. Increasing problems with water scarcity can be related to both global population growth and climate change effects. Predicted sea level rise indicates significant new challenges for coastal protection. Also here flood barriers and different dam structures are needed. The strategies for creating sustainable water infrastructure systems have to comply with a set of engineering, economical, social, as well as environmental assessments and constraints within the framework of the specific projects. Probably the most important perspective is about democracy! Particularly large-scale water resources dam projects have to be planned and implemented in such a way that everyone benefits from the project – everyone from “project-affected people” locally to all those living in regions and countries involved.

Haifa, Israel

Synonyms

Al-Bahr al-Mayyit – the Dead Sea (Arabic); Sea of Asphaltites – (Attic Greek); Yam Ha-Mavet – the Dead Sea (Hebrew); Yam Ha-Melah – the Salt Sea (Hebrew)

Definition

The Dead Sea is a terminal hypersaline lake situated in the land lowest depression of the Jordan Rift Valley between Arabian and Sinai tectonic plates.

Introduction

During the late Pleistocene, the Arabian and Sinai plates were separated by the Dead Sea precursor – Lisan Lake which covered the Jordan Rift Valley entirely about 25,000 years ago. The surface level at that time was about 180 m below mean sea level (bmsl). The modern Dead Sea was formed as a result of recession in the Lisan surface level about 10,000–14,000 years ago (Oren, 2003). Until the beginning of the twentieth century, the seawater level underwent natural fluctuations from about 380 to 420 m bmsl which were associated with interannual variability of precipitation in the Levant region (Kushnir and Stein, 2010). Since the early 1960s, anthropogenic reduction in the Dead Sea freshwater budget outweighed its natural variability because of the countries controlling the freshwatershed of the Dead Sea (i.e., Israel, Syria, and Jordan, Figure 1) increased the water consumption intensively.

Dead Sea, Figure 1 The Dead Sea watershed. Insertion shows profile along the Jordan Rift Valley toward Gulf of Eilat (Aqaba). (Adopted from Niemi et al., 1997.)

Moreover, Israel and Jordan use the Dead Sea water for the production of minerals, contributing to the water deficit. As a result, sea level decreases rapidly (Niemi et al., 1997). Until 1978, the morphology of the Dead Sea consisted of a large and deep northern basin and a smaller and shallower southern basin connected via the Lynch straits (Neev and Emery, 1967). Following the recession of the water level, the entire southern basin would have dried up. However, dikes were erected to transform the southern basin into evaporation ponds for mineral production. During the period 1996–2010, the northern basin surface level decreased at a rate of 1 m/year, and the area shrunk with a rate of $\sim 2.4 \text{ km}^2/\text{year}$. In 2010, the Dead Sea dimensions were: surface level $\sim 424 \text{ m bmsl}$, maximal depth $\sim 295 \text{ m}$, area $\sim 609 \text{ km}^2$, volume $\sim 130 \text{ km}^3$, maximal north-south extension $\sim 50 \text{ km}$, and maximal west-east extension $\sim 16 \text{ km}$. Water salinity was $\sim 280 \text{ g/kg}$, and water density was $\sim 1,240 \text{ kg/m}^3$ at 25°C .

Water budget

During the drought years 1996–2010, the major source of freshwater was still the lower Jordan River: $60\text{--}150 \times 10^6 \text{ m}^3/\text{year}$. The total freshwater inflow (including precipitation and floods) was $265\text{--}335 \times 10^6 \text{ m}^3/\text{year}$. Evaporation rates derived from energy budget were 1.1–1.2 m/year. The low evaporation rate of Dead Sea, compared with fresh lake in similar conditions (1.4–1.5 m/year for the Sea of Galilee, Rimmer et al., 2009), is connected with the high hygroscopic ability of the Dead Sea brine (Krumgalz et al., 2000; Lensky et al., 2005). The total water deficit of the lake is $690 \times 10^6 \text{ m}^3/\text{year}$. About 36% of this amount is due to the activity of the chemical industries in the southern basin of the Dead Sea (Lensky et al., 2005).

Meteorology

The climate in the Dead Sea area is highly arid, with a mean annual rainfall less than 100 mm (Goldreich, 1998).

Air temperature over sea has been observed between 7.5°C and 43.4°C . While typical relative humidity over the Dead Sea is between 33% and 52%. On average, August is the hottest month with air temperature of 33°C and July is the driest (39% humidity). The coldest and most humid month is January with an average temperature of 18°C and 47% humidity. Air temperature changes are closely associated with the arrival of the Mediterranean breeze as well as with the onset of the local breeze. The daily maximal temperature occurs 4 h later than along the Mediterranean coast.

The atmosphere above the sea surface differs from that on land. Air temperature above the sea is colder by about $0.5\text{--}1^\circ\text{C}$ during summer and warmer by about $1\text{--}2^\circ\text{C}$ during winter. Relative humidity above sea is higher by about 4–5%.

Air pressure at the Dead Sea surface is higher than at the mean sea level by about 50 mb.

The typical speed of winds is 4–6 m/s. In general, during summer, winds are mostly northerly. During winter, there is an increase in the southerly winds. During winter, strong winds (10–20 m/s), although rare, occur more frequently than during summer. Westerly winds, associated with the Mediterranean breeze, occur at the same rate throughout the year. They appear in the late afternoon and can reach 20 m/s at midnight. Wind strength diminishes in the morning with the weakest winds occurring around 13:00 (Hecht and Gertman, 2003).

The maximal wind wave heights observed were at 3 m with 8 s period (Hecht et al., 1997).

Chemical composition

The salinity of the Dead Sea water is about eight times larger than that of oceanic water, being supersaturated in respect to halite and perhaps other minerals. Dead Sea water has a particular ionic composition, which is dominated by magnesium chloride unlike oceanic water which is dominated by sodium chloride (Figure 2). The extremely high salinity of the Dead Sea water as well as its unique ionic composition prevents the implementation of inexpensive methods of ocean water salinity measurement. Therefore, in order to characterize the Dead Sea haline structure and variability, one uses its density anomaly from $1,000 \text{ kg/m}^3$ at 25°C (Anati, 1997). This is defined as quasi-salinity.

Since the early 1980s, massive amounts of halite have precipitated from the water column as halite crystals (Gavrieli, 1997). A subject submerged in the Dead Sea water with temperature below 25°C is covered by halite crystals (Figure 3).

Dead Sea, Figure 2 Percentage of ionic concentrations in the Dead Sea water. Δ – ocean water, $\circ$ – Dead Sea water during 2008, $\blacksquare$ – Dead Sea water during 1960–1996, $\square$ – end brines from evaporation ponds. (Data derived from Steinhorn (1981); Gavrieli (1997), Oren (2003), Gertman et al. (2010).)

Dead Sea, Figure 3 Halite crystals accumulated during 2 months on the equipment submerged from the Dead Sea meteorological buoy.

The Dead Sea water ionic composition is unstable due to halite precipitation as well as the water exchange with the evaporation ponds. The Dead Sea water from the northern basin is pumped into the evaporation ponds, where halite continues to precipitate until the salt contents reach some composition when carnallite ($\text{KMgCl}_3 \cdot 6(\text{H}_2\text{O})$) starts to precipitate. The latter is the targeted mineral which is used for potash production. The wasted residual water (about 50% from the pumped volume) is returned to the Dead Sea with a relatively high content of Mg–Ca–Cl (Gavrieli and Oren, 2004).

Hydrology

For hundreds of years the Dead Sea was a meromictic lake (see *Meromictic Lakes*) with stable haline stratification, supported by runoff. Winter convection was limited, and water below the halocline was not affected by atmosphere. As a result of the runoff reduction, the upper-mixed layer (UML) salinity increased, and the gravitational stability diminished. Eventually, during the winter of 1978–1979, the lake water overturned, ending the long-term stable hydrological regime (Steinhorn and Gat, 1983; Anati, 1997). Since then, the lake entered a new phase in which its hydrological regime is either holomictic or meromictic. Since 1979, the meromictic regime is

established twice only after extremely rainy winters: during 1980–1982 and during 1992–1995.

Regardless of regime, deep water temperature remains in the range 22–24°C, while quasi-salinity has increased since 1978 from 232 kg/m³ at a rate of ~0.35 kg/m³ year (Anati, 1997; Gertman and Hecht, 2002). Seasonal thermocline is formed in the middle of March. UML during meromictic winter has low quasi-salinity (200–210 kg/m³) and can be colder than the deep layer due to hydrostatic stability which limits winter convection (e.g., in winter 1993, temperature dropped to 15°C (Beyth et al., 1993)). During summer, the UML reaches maximal temperature (32–35°C), and quasi-salinity value is ~3 kg/m³ higher than at the deep water. The UML thickness during meromictic periods and holomictic summer fluctuates between 15 and 30 m. Convective mixing of the entirely water body occurs during the second half of November in the holomictic regime (Figure 4).

Extremely hot and dense water (up to 44°C and 1,350 kg/m³, Lensky et al., 2005) entering in the southern part of the Dead Sea from the evaporation ponds propagates as gravitation currents northward following the bathymetry. During the summer, this water forms a bottom layer in the entire deep region. The layer is warmer (~0.5°C) and saltier (~0.5 kg/m³) than the main water body layer above it. Double diffusion builds step-like profiles of water properties in the bottom layer (Gertman and Hecht, 2002).

Expected future of the Dead Sea

The sea surface level is expected to decrease in the course of the nearest 500 years. However, some deceleration of the sea level decent has been predicted by different models even if the runoff and industrial water consumption will not change in the future (Yechieli et al., 1998; Krumgalz et al., 2000; Asmar and Ergenzinger, 2002). In all the models, the evaporation rate is inversely proportional to the concentration of ions. Moreover, the integral evaporation decreases with the sea surface area decrease. A critical ionic concentration will diminish the evaporation dramatically when the sea level reaches ~500 m bmsl.

Several proposals were made for stabilizing the Dead Sea water level by connecting the Dead Sea with the Mediterranean or the Red Sea. The main idea is to utilize more than 400 m difference in sea levels to generate hydroelectric energy. Additional profit can be achieved due to desalinization of the seawater on the way to the Dead Sea. In 2005, the governments of the Israel, Jordan, and the Palestinian territories supported by the World Bank agreed to conduct a feasibility study for a canal or pipeline between the Gulf of Aqaba and the Dead Sea along the Arava Valley transporting initially Red Sea water and eventually high salinity end brines (by-product of desalinization) into the Dead Sea. The most evident problems concerning this proposal are: restoration of meromictic stratification, mass precipitation of gypsum, and development of new life-forms (Oren, 2003).

Dead Sea, Figure 4 Vertical profiles of potential temperature (*left panel*) and quasi-salinity (*right panel*) in the deep region of the Dead Sea during February and August 2009.

Summary

For hundreds of years prior to 1950, the Dead Sea surface level was about 400 ± 20 m bmsl. During this period, dilution of the upper layer by the freshwater runoff was sufficient to support stable stratification even during the winter seasons. Anthropogenic reduction of runoff and water consumption for industrial mineral production led to significant changes in dimensions and hydrology of the Dead Sea. Israel Dead Sea Works Ltd. and the Jordanian Arab Potash Co. pump water from the northern part into industrial evaporation ponds located where the southern part used to be. After the extraction of potassium and bromide salts, the remaining extremely dense water is returned to the northern part. During 1978–2010, the northern part sea level descended by 23 m, the area shrank by 58 km^2 , and the volume decreased by 15 km^3 . Gradual salinity increase in the upper layer led to the first overturn in winter 1978–1979. Stable haline stratification, preventing winter overturns, was restored twice after extremely rainy winters of 1980 and 1992, and lasted for 3–4 years each time. The main body water density increased since 1979 from $1,232 \text{ kg/m}^3$ to $1,241 \text{ kg/m}^3$ due to increased ionic concentration. Halite is saturated since about 1980, and permanent precipitation is observed on submerged objects. Increase of ionic concentration leads to decreased evaporation rate; therefore, sea level drop rate is expected to decrease in the future. Different estimates of the future Dead Sea water budget came to a common conclusion that in about 500 years, the sea level will be ~ 500 m bmsl.

DELTAIC SWAMPS

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Definition

A delta is formed where the mouth of the river flows into an ocean, sea, desert, or lake, or simply into a swamp. It is characterized by the main channel dividing into multiple streams or “distributaries.” The water balance of deltaic swamps has some special features differing from usual river basins, reservoirs, and lakes. The main differences are the variable area of swamps and the unsteady flow distribution. A river basin is usually well defined, and the area, for practical purposes, is constant. But in a swamp, the area changes continuously in response to inflow, precipitation, and evapotranspiration. These, in turn, themselves, vary during the year and from one year to another.

Deltaic swamps: examples and description

A well-known example of a deltaic swamp is the Okavango Delta in Botswana. A peculiarity of the Okavango Delta is that the outflows are a very minor fraction of the total input (inflow plus precipitation) due to the evapotranspiration losses from the large area. The outflow appearing in the Boteti River, for example, amounts to only about 2% of the input. Thus, predication of outflow from the Delta is not as easy as from river basins generally.

In addition to this, the flow distribution of the Delta, though partly controlled by vegetation, seems to change in response to earth tremors. Much attention has, in the past, been paid to blockages of the Delta channels by floating plant material. From a boat, these blockages seem dramatic, but we now know that the bulk of flow through the swamps takes place outside the open water channels. It seems to follow that channel blockages are not, in themselves, the main or most immediate agents of change in the distribution of flow.

Scattered throughout the delta are thousands of islands, the number actually estimated at about 50,000, each island being unique in the types of trees it supports (jackalberry, mangosteen, knobthorn, date palm, and fig). Most of the smaller islands have been formed by the fungus-growing termites, and their activity not only raises patches of land above the flatness of the Kalahari but also enriches the soil.

The Delta’s wildlife includes lions, leopards, elephants, buffalo and rhino, cheetah, giraffe, hippopotamus as well as antelopes, zebra, buffalo, baboons, monkeys, hyenas, and crocodiles.

The celerity of the flood wave through the Delta from Mohembo to Maun is of the order of 5 cm/s. Electrical conductivity measurements of the swamp waters show that the average velocity of flow is even less than this. Such slow movement indicates that most of the flow takes place through the swamps outside the main channels although these swamps might have been assumed to be already “blocked” by vegetation.

Observations and simple calculations of water balance show that the area of the swamp is at its maximum during the months of June and July and reaches its minimum in December and January.

Deltaic Swamps, Table 1 Worldwide distributed large deltas

Name	Area in km ²	
Amazon	467,000	Brazil
Chao Phraya	11,000	Thailand
Danube	2,700	Romania
Ebro	600	Spain
Ganges-Brahmaputra	106,000	Bangladesh/India
Huang	36,000	China
Indus	40,000	Pakistan
Irrawaddy	21,000	Burma
Lena	30,000	Russia
MacKenzie	13,500	Canada
Mahakam	5,000	Indonesia
Mekong	94,000	Vietnam
Mississippi	29,000	USA
Nile	15,000	Egypt
Niger	19,000	Nigeria
Orinoco	20,000	Venezuela
Po	13,400	Italy
Rio Grande	8,000	USA
São Francisco	700	Brazil
Senegal	4,300	Senegal
Yangtze	66,700	China

After entering the Delta, the water spreads out over an area of the cone which varies according to season and from which evaporation and transpiration (considered as one item – evapotranspiration) takes place.

As the water level rises and falls and the area increases in response to changes in inflow and to rainfall and evapotranspiration, so the amount of water in storage will change. We therefore come to the basic equation for the Delta as a whole and for each part of it:

$$\text{Inflow} - (\text{Evapotranspiration} - \text{Rainfall}) \\ \times \text{Swamp Area} - \text{Increase in Storage} = \text{Outflow}$$

Some examples of worldwide distributed large deltas are given in [Table 1](#).

DEW PONDS

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Definition and introduction

The subject of dew ponds is one of perennial interest after more than 200 years of research since Gilbert White noticed the phenomenon of upland ponds in southern England and the Yorkshire area where one pond only leaked once in 400 years and only did so because roots of rushes penetrated the clay.

Dew ponds are artificial, saucer-shaped depressions commonly found on upland surfaces in northwest Europe, most notably in southern England. They are used to provide convenient small-scale watering sources for sheep

and cattle in otherwise dry areas. Large-scale domestication of these animals began in Africa during the late Paleolithic, and following the end of the last ice age, animal husbandry accompanied human immigration into northwest Europe during the Mesolithic (around 8000 BC) and especially in the Neolithic (5000–2000 BC). During the nineteenth century, however, the widespread extension of piped water supplies caused dew ponds to fall into disuse. In the late twentieth century, however, a sociological trend toward a simplification of life systems has led to the revival of the old facilities (see [Figures 1](#) and [2](#)).

The dew pond is still important today particularly in the high chalk country of Surrey, Sussex, Kent, and Wiltshire in southern England. It is a fact that the ponds rarely run dry, and this was confirmed by local farmers to the author on a visit to study the ponds.

Construction

The ponds are normally saucer-shaped, about 15 m in diameter, and 1 m deep at the center usually with a substantial catchment of some 30-m diameter. To be classed as a dew pond, except for its own natural catchment, there should be no ingress of water from springs, channels, or any form of drainage into the pond. The essential ingredient of the dew pond is a completely waterproof layer of puddled clay, usually of about 30 cm thick, over a 30-cm layer of straw ([Figure 1](#)). The clay is not allowed to dry out and crack and hence break the seal. At the turn of the twentieth century, the puddling of the clay was often done by oxen but today puddling is performed by caterpillar tractor. Otherwise, construction methods have changed little over the centuries except that, when a pond is restored, a butyl rubber or polythene liner is sometimes used between the straw and the puddled clay layer (Belden 1997, Private communication and discussion, Sussex Downs Conservation Board; Larkin, 1997, Private communication and discussion, Brighton and Hove Environmental Services).

Restoration of ancient dew ponds in southern England is in progress today, with the support of various environmental groups, notably the Sussex Downs Conservation Board and the Brighton Environmental Services. Using old maps, these organizations inspected over 230 possible sites where dew ponds were known to have existed at one time. From the survey, only 68 sites proved to be genuine dew ponds, of which 40 still held water, but only 14 were being used for stock watering (Carpenter, 1995). [Figure 2](#) shows one of a selection of the 30 dew ponds restored to date. Today, for the interested including tourists, information is displayed, in the form of a notice, giving some notes on dew ponds for the public's information throughout the South Downs at selected dew ponds.

Although [Figure 1](#) shows one method of construction of a dew pond and although it is basically the method adopted in the restoration of ponds today, it has not been the only one in the past, and over the last two centuries, there have been several variations, depending mainly on the part of

Dew Ponds, Figure 1 Cross-section of a typical dew pond.

Dew Ponds, Figure 2 Dew pond in Shoreham, England.

the country in which the dew ponds were constructed. Martin (1915, 2002) shows that straw and puddled clay were used in one position or another and often in a series of layers of (from the bottom) straw, clay, straw, clay, straw, and clay (giving six layers); clay, straw, and chalk rubble; quicklime, clay, quicklime, straw, and broken chalk; chalk puddle only; straw, clay, and stones; and lime-tempered clay, straw, and loose rubble or broken chalk.

History

It is believed that dew ponds date from prehistoric times, possibly from the Neolithic or even Paleolithic periods. In both of these periods, the water table on the chalk of the Sussex Downs was probably much the same as it is today. The ponds were to be found high up in the Downs

where stock required to be watered rather than exposing them to a long trek down to the valleys below.

Gilbert White, the naturalist, mentions the ponds in his writings in 1776 when he noted that:

the little ponds on the chalk hills were not known to fail even when ones in the vales were dried up. White wrote: Now we have many such little round ponds in the district [Selborne]; and one in particular on our sheep-down ... [contains] perhaps not more than two or three hundred hogsheads of water [300 hogsheads = 73,000 litres] yet never is known to fail, although it affords drink for 300 or 400 sheep and for at least twenty head of large cattle besides; and in spite of evaporation from sun and wind, and perpetual consumption by cattle, yet [these ponds] constantly maintain a moderate share of water, without overflowing in the wettest seasons, as they would do if supplied by springs. By my journal of May 1775, it appears that the small and even considerable

ponds in the valleys are now dried up, while the small ponds in the very tops of hills are but little affected. Can the difference be accounted for from evaporation alone, which is certainly more prevalent in bottoms? or rather, have not those elevated ponds some unnoticed recruits, which in the night-time counterbalance, the waste of the day, without which the cattle alone must soon exhaust them.

Clearly, White was intrigued by the ponds, and did he too think of dew supplementing them by night but was too professional to say so?

Theory

Dew consists of drops of water, the condensation of atmospheric water vapor on any surface where the temperature has fallen below the dew point. The latter is defined as the temperature at which the saturation pressure equals the vapor pressure. If the ambient temperature is below 0°C, it becomes the frost point. A dew point hygrometer may be used to determine surface dew point. More often, dew point is simply determined with a psychrometer (wet and dry bulb thermometer).

Dew is often the only source of water available for plants and animals in desert regions. In northwest Europe, dry areas exist, especially on the Upper Cretaceous chalk formation (widespread in southern England, northern France, and Germany) which is homogeneously porous and consequently well drained, even though there is abundant rainfall (750–1,000 mm). Thus, there is a genuine need for dew ponds. However, the term is based on a misleading deduction, dating from antiquity. Walford (1924) reported it as “the great dewpond myth.” Alas, the maximum experimental dew accumulation is only 50 mm year⁻¹. Earlier experiments noted by Pugsley (1939) were carried out by Slade (1877), Hubbard and Hubbard (1904), and by Martin (1915), but all led to the same conclusion. Nevertheless, the term enjoys the priority of antiquity and is therefore permanently established.

The explanation is that in a region of annual precipitation up to 1,000 mm, rather evenly distributed throughout the year as a rule, and where the annual evaporation is only 450 mm, there should be an abundant water supply except in major drought cycles (as in 1994–1997, the driest in centuries). However, there are often cases where the least rainfall occurs when there is the greatest evaporation. In these cases, mists and fogs may account for filling the ponds. There seems scope, however, for further research. Slade (1877) notes that “shepherds reported that some dewy nights had added 2.5 cm to the water measurement of the afternoon before.” Nevertheless, the meteorological setting is significant. In a region of prevailing westerlies, the often nearly saturated humid air mass is forced to rise 200–300 m as it encounters the Downs, where the air temperature may fall below the dew point and a “scotch mist” may result.

Conclusion

The principle, construction, and operation of dew ponds still invite interest today in understanding them. One

may often hear the view that “dew can never feed a pond; it is formed from the moisture in the air being in contact with the cooled earth’s radiation at night.” Researchers have spent night after night on the banks of ponds watching for dew being formed even on the banks often without success. Yet a young farmer told the author that in his time and his father’s and grandfather’s time, the farm dew pond had never been depleted.

Many studies have been carried out into dew ponds since Gilbert White’s work in 1775 in Selborne, England; but, work still continues, although today the dew ponds are mainly artificial, and many are constructed for the tourist’s pleasure. However, some of the original English dew ponds still in operation are reputed to go back in time to Early Man.

Transboundary Waters: Rivers, Lakes, and Groundwaters

DISSOLVED OXYGEN IN ICE-COVERED LAKES

Arkady Terzhevik¹, Sergey Golosov²

¹Laboratory of Hydrophysics, Northern Water Problems Institute, Karelian Scientific Centre, Russian Academy Sciences, Petrozavodsk, Russia

²Laboratory of Hydrology, Institute of Limnology, Russ. Acad. Sci., St. Petersburg, Russia

Definition

DO deficit is a difference between the actual amount of dissolved oxygen in lake or sea water and the saturation concentration at the temperature of the water mass sampled.

Oxygen depletion is a phenomenon that occurs in aquatic environments as dissolved oxygen becomes reduced in concentration to a value detrimental for aquatic organisms living in the system. It may provoke formation of a so-called “dead zone.”

Dead zone is an anaerobic area in a water body where existence of majority of aquatic organisms is impossible.

Fish kill also known as *fish die-off* and as *fish mortality*, is a localized die-off of fish populations which may also be associated with more generalized mortality of aquatic life. The most common cause is reduced oxygen in the water.

Under-ice warming is the increase of water temperature during the ice-covered period that occurs mainly in shallow (up to 10–15 m in depth) water bodies due to heat inflow from sediments.

Introduction

One of the main parameters, which allow to assess the lake water quality, is dissolved oxygen (DO). The evolution of the oxygen regime in the lakes is usually controlled by the following processes: (1) gas exchange through the water–air interface; (2) vertical turbulent mixing within a water column; (3) photosynthesis that contributes the increase of DO concentration in water; (4) respiration of water organisms, bacterial oxidation of organic matter, chemical oxidation of H_2S , Fe^{2+} and other reduced inorganic substances leading to a decrease of the DO content in water; and (5) oxygen uptake by bottom sediments. During the period of open water, the upper layer of a lake (epilimnion) is, as a rule, well saturated due to the permanent gas exchange between water and atmosphere. In lower layers, seasonal DO dynamics is determined by the vertical turbulent mass transfer and biochemical consumption. In winter, when a lake is ice covered and isolated from atmosphere, intensive vertical mixing and photosynthesis are practically absent; therefore, the oxygen uptake due to biochemical destruction of organic matter in water and in sediments may lead to the oxygen deficit there, sometimes to its complete depletion and to the development of the fish kill effect (Barica and Mathias, 1979; Greenbank, 1945; Hargrave, 1972; Hutchinson, 1957). As the ice-covered period in boreal lakes lasts for 180–190 days, this, in turn, may endanger the whole lake ecosystem.

The winter DO regime phenomenology

Let us consider conditions in a shallow lake before the ice-covered period starts. The water column is well chilled and rich of DO (about 94–96% of saturation, see, e.g., Terzhevik et al., 2009) due to heat loss into the atmosphere and strong wind mixing. If biological productivity of a lake is low and amount of newly formed in autumn organic matter (OM) is negligibly small, DO content varies depending on water temperature and is consumed only in the very vicinity of bottom due to bacterial activity. Hutchinson (1957) suggested an empirical relation to roughly estimate the saturation DO value C^* as a function of water temperature T ,

$$C^* = 14.6221 - 0.407699T + 0.00812934T^2 - 0.000079448T^3 \quad (1)$$

which allows to calculate 95% values for the whole range of water temperatures typical for ice-covered lakes (Figure 1).

In real life, this hypothetical case practically never occurs. All lakes are affected, to greater or lesser extent, by inflow waters coming from their catchment areas and by human activities, which can be considered as sources of nutrients and provoke lakes bioproductivity. Depending on its amount, newly formed OM, stored in near-bottom layers of local deepenings and upper layers of sediment, may cause DO consumption because of its bacterial destruction that leads to the formation of DO deficit or depletion.

Roughly speaking, one may distinguish four stages of the winter DO regime. The first stage precedes the ice cover development and can be called “winter cooling.” On the background of water cooling, the newly formed in autumn OM sinks toward a lake bottom, being heavier than surrounding water. Depending on heat loss and wind mixing, the length of this stage varies and affects the DO content – the longer former, the higher latter. Thus, the first

Dissolved Oxygen in Ice-Covered Lakes, Figure 1 DO values of 95% saturation corresponding to the initial water temperatures (upper left part, 0.5–2°C) and to the bottom water temperatures within a period of under-ice warming by heat transferred from sediments (lower right part, 3–5°C) typical for shallow ice-covered lakes.

stage is a prerequisite for the DO deficit/depletion development.

The second stage starts after ice cover formation and can be characterized by DO consumption throughout the whole water column, minimal in surface layers and maximal in bottom layers. Within several weeks, DO content in near-bottom water over local hollows where OM is located may drop down for 80–90% of initial values or even disappear altogether (Figure 2a).

The main reason for such a case is the different rate of bacterial DO consumption over local deepenings and declined bottom. Here, bacteria mineralize not only OM stored in the upper layer of bottom sediment but also in the near-bottom waters. Their activity depends on the water temperature, which is higher there compared to shallower waters and actively grows during the second stage due to heat transferred from lake sediment. Over the declined bottom, the vertical DO profile looks different, that is, a drastic decrease can be observed only in the very vicinity of lake sediment (Figure 2b). This is a result of OM absence in the near-bottom waters of such areas.

The third stage starts when the vertical temperature profile becomes nearly linear and quasi-stationary, that is, heat flux from sediments is balanced by heat loss from water to ice. By then, the near-bottom DO deficit is formed (the case for some shallow oligotrophic and mesotrophic lakes). In lakes where OM amount is very high (eutrophic and hypereutrophic lakes), the deficit transforms into depletion with eventual appearance of the dead zone, which may, if a lake depth is small, spread out through the whole water column, leading to the fish kill.

During the third stage, DO content decreases not only in the lower part of a water column but also in the middle layers. This occurs due to the molecular DO flux directed from relatively “DO-rich” layers toward a lake bottom where DO content is much lesser. The anaerobic zone, if any, stops to grow as DO consumption on its upper

boundary is compensated by the molecular DO flux. Such situation usually lasts until late winter. By then, the snow cover disappears, and solar radiation starts to penetrate through ice into water, initiating the under-ice convection.

To this very moment, the last – fourth – stage starts. As lake productivity was suppressed during winter, water transparency is high, and solar radiation penetrates deep into the water column, increasing its temperature. As upper layers are heated stronger, it leads to the development of convective instability and eventual mixing. Within this convectively mixed layer, DO content is quasi-uniform (Figure 2). If a lake is shallow enough, convection may reach its bottom. Because of absence of DO external sources, absolute values of DO content, being distributed within a larger volume, get smaller. The fourth stage is the shortest and lasts for a couple of weeks. Once the ice cover disappears, aeration of the water column due to interaction with atmosphere and wind mixing takes place (Figure 2, profiles 6). DO deficit/depletion and dead zones vanish. During the open-water period, it may appear again, but this is a different story.

Summary

Because of its numerous negative consequences, DO depletion may endanger the ecosystems of shallow lakes. Therefore, the development of forecasting methods is of vital importance. Among others, numerical modeling of seasonal DO dynamics in water bodies looks very promising. During the last decades, some positive experience has been collected (Bell et al., 2005; Fang and Stefan, 1997; 2009; Golosov et al., 2007). One of the bottlenecks for such models is poor knowledge on empirical (not universal) parameters included into the models. Primarily, it concerns the bacterial DO consumption rate. To resolve a problem, the targeted field observations are needed. An example of observational data use is given below. Data itself are records of DO content at different depths of a water column in a shallow mesotrophic lake registered regularly

Dissolved Oxygen in Ice-Covered Lakes, Figure 2 Vertical DO profiles in a shallow ice-covered lake: 1 stands for the last days before ice cover formation, 2 for early winter, 3 for mid-winter, 4 before under-ice convection, 5 after convection, and 6 after ice cover disappearance; (a) over local deepenings, (b) over slopes. Dashed line marks the water–sediment interface. Based on unpublished data of NWPI.

Dissolved Oxygen in Ice-Covered Lakes, Figure 3 Temporal dynamics of the DO consumption rate $\gamma = \ln(C/C_0)/t$, see the text: 1–3 stands for three winters over local deepenings, 4–5 for slope locations; (a) local deepenings, (b) slope. Based on unpublished data of NWPL.

(1 min apart) throughout all winter, which are used to calculate depth-average values of DO concentrations.

Typically, the development of any non-conservative substance C in time can be described as,

$$\frac{\partial C}{\partial t} + u \frac{\partial C}{\partial x} + v \frac{\partial C}{\partial y} + w \frac{\partial C}{\partial z} = (D_t + D_m) \frac{\partial^2 C}{\partial z^2} \pm S. \quad (2)$$

Here, u , v , and w are current vector components along corresponding axes; D_t and D_m stand for turbulent and molecular diffusivities, respectively; $S = \gamma C$ is a term describing sources and/or sinks of non-conservative substance; γ is the substance consumption rate. Scaling analysis (see, e.g., Terzhevik et al., 2009) allows to simplify Equation 2 as,

$$\frac{\partial C}{\partial t} = -\gamma C, \quad (3)$$

with a corresponding analytical solution

$$C = C_0 e^{-\gamma t}. \quad (3a)$$

Here, C_0 is the initial value of substance C , in our case prescribed as DO concentration at the moment of ice cover formation. The DO consumption rate γ can be estimated as an inverse problem of Equation 3a, that is, $\gamma = -\ln(C/C_0)/t$, given known values of the initial and final DO concentrations for the period t , in seconds.

Figure 3 demonstrates the use of observational data to evaluate temporal dynamics of the DO consumption rate γ in a shallow ice-covered lake. As one can see, the most drastic consumption occurs in first weeks of the ice-covered period. For the rest of the observational period, the consumption rate can be considered as quasi-constant, and this value can be used for estimates of the seasonal change of DO content.

Of course, this text cannot be considered as a full description of the winter DO regime in shallow ice-covered lakes. The authors have briefly presented current

knowledge and some results of their 10-year research on the problem considered. It is quite plausible that the actual cause of the DO dynamics in some ice-covered lakes may deviate to some extent from the general picture, which presents only the main mechanisms that govern the process.

DOUBLE-DIFFUSIVE CONVECTION IN LAKES

Bertram Boehrer
Department of Lake Research, Helmholtz Centre for
Environmental Research – UFZ, Magdeburg, Germany

Definition

Double-diffusive convection in lakes is a pattern formation in density stratified lakes, which results from largely different diffusivities of dissolved substances and heat.

Double-diffusive convection has been investigated in laboratory experiments and has been documented in tropical lakes (Lake Kivu: Newman, 1976, Lake Nyos: Schmid et al., 2004), but also in meromictic lakes of the temperate climate zone (von Rohden et al., 2010).

Introduction

When two physical quantities of different diffusivities contribute to density, double-diffusive convection can occur. Such features are visible if heat is one of the factors, as the diffusivity of heat is two orders of magnitude higher than of dissolved substances. However, from lab experiments, it is known that double-diffusive features can also occur at an interface of solutions of different substances (e.g., salt and sugar). For a general overview of double-diffusive effects, see the publication by Turner (1995), with a focus on limnological implications see the chapter by Imboden and Wüest (1995).

Of special interest is the case when one of the components keeps the overall stratification stable, while the other component delivers a density contribution, which weakens the density gradient. The stability ratio of the stabilizing effect over the destabilizing effect R_ρ classifies this system. For overall stable configuration, $R_\rho > 1$. Double-diffusive convection is in particular visible if the destabilizing component is of the same order of magnitude as the stabilizing effect, i.e., $1 < R_\rho < D_T/D_S$, the ratio

of the diffusivities of the respective quantities of heat (or temperature T) and dissolved substances (salinity S) with increasing intensity when approaching unity. Two cases can be distinguished (Figure 1).

Considering a two-layer system, with the stabilizing component diffusing faster than the smaller, opposing effect component, e.g., a cold but fresh water layer overlain by a hot water layer of higher salinity (so-called finger regime). Hence

$$R_{\rho(\text{finger})} = \frac{\alpha dT/dz}{\beta dS/dz}$$

where $\alpha dT/dz$ is the density gradient along the vertical axis z due to temperature T , while $\beta dS/dz$ represents the density gradient due to dissolved salt. $\alpha = \frac{1}{\rho} \frac{\partial \rho}{\partial T} = -\frac{1}{\rho} \frac{\partial \rho}{\partial T}$ is the thermal expansion coefficient, and $\beta = \frac{1}{\rho} \frac{\partial \rho}{\partial S}$ is the coefficient of haline contraction.

A small density disturbance of salt water at the interface proceeds little into the lower layer and hence is exposed to stronger heat exchange than at its original position. Due to the higher diffusivity of heat compared to salt, density is continuously gained by the droplet, and it proceeds into the lower layer, leaving a fine line of increased salinity in its wake. Many droplets next to each other explain the term “finger” regime.

The opposite case is called the “diffusive regime.” Salt water lies under a fresh water layer of lower temperature. The density ratio now is defined as

$$R_{\rho(\text{diffusive})} = \frac{\beta dS/dz}{\alpha dT/dz}.$$

Heat is crossing the interface, and each layer is convectively driven from this interface. In this configuration, there is no limit of the vertical convective motion. An interesting case appears when we have to deal with a continuous stratification. Then the convection is

Double-Diffusive Convection in Lakes, Figure 1 Double-diffusive convection at an interface between two layers of different properties. Left panel: finger regime, right panel: diffusive regime. Water motion is shown by solid arrows, while heat diffusion is displayed with open arrows.

confined to a certain layer thickness, where the background stratification does not permit a further ascent. A series of convection cells appears on top of each other, leaving a staircase of steps in the profiles of conductivity (and temperature, see Figure 2).

Such steps can develop from originally smooth profiles, e.g., by a seasonal temperature forcing (von Rohden et al., 2010). The staircase is the consequence of a pattern formation. A length scale for the steps can be derived (e.g., Kelley, 2003), which coincides with observations reasonably well (see Schmid et al., 2004); even thin layers extend over hundreds of meters horizontally (von Rohden et al., 2010). Double diffusion forces a highly enhanced vertical transport of heat and substances and hence has environmental implications.

However, double-diffusive convection does not only occur in the monimolimnia of meromictic lakes, but it is also present when intrusions of different salt concentration/composition and temperature proceed into a stratified lake. Propagation speed and vertical spreading can be controlled by double-diffusive effects. In other cases, biogeochemical transformations have been shown to enhance double-diffusive effects (Boehrer et al., 2009). Even the layered sedimentation of different

minerals has been brought related to double diffusion. An overview of possible implications of double diffusion can be found in Turner's (1995) text and the monograph by Brandt and Fernando (1995).

DROUGHTS AND WATER MANAGEMENT IN ENGLAND AND WALES: WITH PARTICULAR REFERENCE TO RESERVOIRS AND LAKES

Terry Marsh
 Centre for Ecology & Hydrology, Gifford Wallingford,
 Oxfordshire, UK

Introduction

Reservoirs and lakes are major sources of water supply, power generation, and ecological diversity; they also have considerable amenity value and commonly provide extensive recreational opportunities. In most countries, they constitute a primary component in water resources management systems which help bolster resilience to periods of drought. During dry episodes especially, careful stewardship and management of water bodies is essential to ensure that, with temperatures and water demand increasing, drought impacts on both human and wildlife populations are moderated. Here, the impact of droughts over the last 50 years on reservoirs and lakes in England

and Wales is reviewed in the context of refinements in water management strategies and the challenges posed by global warming.

Background

England and Wales has a temperate climate with rainfall well distributed throughout the year but with a tendency towards an autumn and early winter maximum. With a 1971–2000 mean annual rainfall of 1,112 mm, it is one of the wettest countries in Europe but this disguises very wide spatial variations. In the driest parts of Southeast England, the annual average falls below 500 mm while annual totals can be an order of magnitude higher in the hills of Northwest England. Average annual evaporation losses span a relatively narrow range – typically 350–550 mm – with around 75% of the total normally occurring during the summer half-year (April–September). Correspondingly, the bulk of the replenishment to reservoirs occurs during the winter half-year. During the late spring, summer, and early autumn, water demand normally exceeds replenishment and reservoir stocks decline.

There are estimated to be around 200,000 ha of permanent lakes and nearly half a million small ponds which constitute an integral part of the UK landscape and, together, represent around 20% of the surface area of the country (National Ecosystem Assessment, 2011). Many of the larger natural lakes are used for water resources purposes, and they form a significant minority of the more 400 reservoirs in England and Wales. Most large reservoirs are components in complex regional water supply networks (see below) and many are multifunctional: moderating flood risk, generating hydropower, and providing recreational opportunities.

In the wet, impermeable uplands of the West and North of the country, most reservoirs are gravity-fed while off-line pumped storage impoundments provide a major component of the overall water storage in the drier and flatter East and South of the country where the terrain, and permeable nature of the bedrock, affords much fewer opportunities for reservoir construction.

In broad terms, the primary water management challenge in England and Wales is that population, commercial activity, and intensive agriculture – which generate the highest water demand – are concentrated in the driest parts of the country where, on average, annual rainfall totals only modestly exceed evaporation losses. Correspondingly, innovative and flexible water management strategies are required to maintain water supplies – particularly during extended periods of rainfall deficiency.

What is a drought?

Droughts are a natural component of climatic variability. The concept of a drought is generally well understood but translating that understanding into a robust quantitative mechanism for indexing drought extent and severity remains a considerable challenge. This reflects the difficulties in quantifying a phenomenon which varies in its causation, extent, duration, intensity, and, particularly, its

range of impacts. Useful distinctions can however be drawn between meteorological droughts defined essentially on the basis of rainfall deficiency; hydrological droughts – where accumulated shortfalls in runoff and aquifer recharge are of primary importance; and agricultural droughts – where the availability of soil water through the growing season is the critical factor.

In relation to water management, hydrological droughts – and the attendant paucity of runoff and aquifer recharge – are of most direct significance, along with the scale of the water demand that the available resources have to service. In addition, the ability of reservoirs and lakes (and downstream rivers) to sustain a healthy and diverse aquatic environment during drought episodes has assumed an increasing significance over the last 20 years.

Drought in England and Wales does not constitute the very real threat to lives and livelihoods that it is throughout much of the world but reconciling the, often competing, demands for water while maintaining a healthy aquatic environment presents considerable scientific, engineering, and organizational challenges.

Droughts impact on lakes and reservoirs as a consequence of reduced inflows, reduced surface rainfall, and increased surface water evaporation losses; high water temperatures can also contribute to water quality problems. The size of reservoirs, as well as the water demands on them, is reflected in the duration of drought to which they are most vulnerable. A combination of modest rainfall and high evaporative demands means that summer droughts often impact severely on agricultural reservoirs and small water bodies. Open-water evaporation losses are influenced by temperatures, windspeed, sunshine hours, and humidity and can appreciably exceed potential evaporation losses; losses may exceed 500 mm during an arid spring and summer. Evaporation losses on this scale during periods of rainfall deficiency can be sufficient to dry up many ponds and shallow lakes. They can also impact appreciably on large reservoirs stocks – accounting for up to 15% of capacity in some lowland impoundments. However, most large reservoirs (and regional groups of reservoirs that are operated as a single resource) can normally withstand even exceptionally dry summers and, generally, are most vulnerable to winter droughts especially when the rainfall deficiencies extend over two, or more, successive years (see below).

Droughts and their impact on water resources

The UK's vulnerability to extended periods of rainfall deficiency was well demonstrated during the late 1950s and early 1960s. An intense drought in 1959 affected most of the country and was followed, in 1962–1965, by three of the driest winters in the last 100 years. These episodes, together with projections of a doubling in water demand over the latter half of the twentieth century, stimulated the creation of the Water Resources Board – charged with developing a strategic blueprint for water resources development in England and Wales. This heralded a period of increased reservoir construction and the

development of more sophisticated water resources management strategies – incorporating increasing usage of regional water transfers, river regulation, conjunctive use of surface and groundwater resources, and, generally, more integrated regional water management.

The resilience of the UK's water resources infrastructure was severely tested during the extremely intense drought of 1975/76 (Rodda and Marsh, 2011). The period May 1975–August 1976 was the driest for any 16-month sequence in a rainfall series for England and Wales that extends back to 1767 (Wigley et al., 1984). Through the spring and exceptionally hot summer of 1976, overall reservoir replenishment rates were the lowest recorded in the twentieth century. The drought had widespread environmental and agricultural impacts (Doornkamp et al., 1980; Rodda and Marsh, 2011) and water resources were exceptionally stressed during the late summer and early autumn. Reservoir stocks fell to only around 10% of capacity in a few parts of Southwest England, and hose-pipe bans extended across most of the country by July. As resources dwindled, additional water conservation measures were included in the 1976 Drought Bill which was fast-tracked through Parliament. In the event however only local, and very temporary, recourse to rota cuts or standpipes for public water supplies were needed (and

these were due largely to the limited interconnectivity of local water supply networks) before exceptional autumn rainfall brought an unusually rapid termination to the drought.

A short but intense April–August drought in 1984 impacted primarily on Northern and Western Britain (Marsh and Lees, 1985). Steep declines in reservoir stocks through the spring and summer, exacerbated by open-water evaporation rates of >5 mm per day, resulted in very depressed late summer reservoir levels (see Plate 1). Water conservation measures were widely implemented before the drought conditions were alleviated during a notably wet autumn. Generally, the 1980s was a relatively wet decade but the very dry winter of 1988/89 generated significant public and political concern about the UK's vulnerability to drought. One consequence was the initiation of a National Hydrological Monitoring Programme (Anon, 2011) to routinely collate and analyze a range of hydrometeorological variables, and document both hydrological variability and water resources status. Included in the program was the monitoring of reservoir stocks for a representative network of major reservoirs throughout the country. The aggregated stocks for England and Wales provide a convincing index of the overall impact of drought episodes on water resources (see Figure 1).

Droughts and Water Management in England and Wales: With Particular Reference to Reservoirs and Lakes, Plate 1 Haweswater reservoir in August 1984 (Photo credit: Jackie Carr).

The 1990s were characterized by sustained wet and dry episodes and two protracted droughts which stressed both reservoir stocks and groundwater resources (Marsh et al., 1994; Marsh, 1998). Runoff over the September 1990–August 1992 period was less than 50% of average in parts of Eastern England and many reservoirs failed to refill over the 1991/92 winter. In the ensuing spring, the water resources outlook was fragile throughout much of Western Europe (Marsh, et al., 1994). Fortunately, the summer and autumn of 1992 were notably wet and drought stress was largely eliminated through the winter of 1992/93.

The winter of 1994/95 was also wet and water resources were very healthy entering the spring. However, from the beginning of April, the driest 5-month sequence on record for England and Wales resulted in an exceptionally steep

decline in reservoir stocks. A heat wave in August increased water demand and overall reservoir stocks fell below 50% of average by the end of the summer. In Northwest England, the combined stocks for a group of reservoirs servicing major conurbations to the south fell below 15% of capacity (Figure 2). This serves to emphasize that, in circumstances where demand is high and rainfall extremely low, the critical period for a major resource can be relatively short. The dry and hot summer also resulted in reduced oxygen levels and widespread water quality problems in lakes and reservoirs. Entering the autumn, almost 20 million people were affected by hose-pipe bans and, though varying substantially in intensity, drought conditions continued through to 1997 by which time, groundwater levels in the major aquifers were very

Droughts and Water Management in England and Wales: With Particular Reference to Reservoirs and Lakes, Figure 1 Overall stocks (% of capacity) for a representative network of large reservoirs in England and Wales.

Droughts and Water Management in England and Wales: With Particular Reference to Reservoirs and Lakes, Figure 2 1994–1996 reservoir stocks (% of capacity) for a group of reservoirs in Northwest England (the broken trace indicates mean monthly stocks).

depressed. This restricted the options available to water managers to relieve pressure on surface water storages.

The 1995–1997 drought's termination heralded the wettest 5-year sequence on record for England and Wales, but early in 2003, a further drought episode was initiated, and became severe through the exceptionally warm summer. The drought's impact was extensive and diverse, affecting much of Western and Southern Europe. By the autumn, large rainfall deficiencies extended across all regions of the country (Marsh, 2004) but the drought was most severe in Southeast England where record temperatures contributed to exceptional rates of open-water evaporation. Many ponds dried up, wetlands contracted, and, with water and oxygen levels low, many fish rescues were required. Nonetheless, despite the second driest February–October on record, overall stocks in the reservoirs supplying London's water needs remained above 50% of capacity apart from a brief interlude during September and no restrictions on water usage (other than spray irrigation) were required. This demonstrates a considerable degree of resilience to within-year rainfall deficiencies when the wetness of the preceding winter ensures that reservoir stocks are near to capacity and groundwater (a significant component of water supply in Southeast England) levels close to seasonal maxima entering the spring.

The particular importance of winter rainfall was again underlined during the protracted drought of 2004–2006 when, across Southern Britain, November–April rainfall totals were depressed over successive years. Correspondingly, a substantial proportion of reservoirs failed to refill before the spring recessions became established in 2005 and 2006 (see Figure 3). By the summer of 2006, with groundwater levels also notably low, hosepipe restrictions applied to 13 million consumers and many ponds (see Plate 2) and groundwater-fed wetlands were greatly diminished in size.

Water resources and drought management in England and Wales

Water management measures to counteract drought fall broadly into two categories: strategic and tactical – both attempting to influence the balance between water demand and available resources.

The former group embraces the establishment of appropriate legislative and regulatory frameworks augmented by suitable planning controls (e.g., to moderate development in water-stressed areas). In England and Wales, the Department for Environment, Food and Rural Affairs (Defra) and the Welsh Government are responsible for water resources policy while management is principally the responsibility of the Environment Agency which works with the water supply companies to regulate the supply of water and protect the environment.

The statutory framework establishes a long time horizon within which to address the threat of drought. All water supply companies are required to prepare drought plans outlining how they propose to manage water resources (including demand) in the future without detriment to the environment (Environment Agency, 2011). Also falling into the strategic category are: improvements in drought forecasting capabilities and water exploitation strategies, medium-term measures to moderate demand (e.g., the promotion of more efficient domestic, industrial, commercial and agricultural water use; bearing down on mains leakage rates, increasing the proportion of domestic metering, and introducing smart water use tariffs which reward moderate usage).

The tactical category includes an escalating series of contingency measures to be introduced as drought conditions intensify (Walker, 1998). They are directed toward conserving stocks in circumstances where there is likely to be great uncertainty regarding when a drought episode will end. The measures address mechanisms for supplementing

available water supplies, constraining demand, and engaging with stakeholders to agree to an equitable partitioning of limited resources between often competing needs, while ensuring, so far as is practicable, that the environment and aquatic habitats are protected during periods of drought. Typically these involve media campaigns to moderate demand, and a temporary relaxation of statutory conditions on water abstractions, for example to reduce compensation releases from reservoirs. Where an exceptional shortage of rain can be demonstrated, water companies can apply for Drought Permits or Drought Orders (Department for Environment, Food and Rural Affairs, 2011). These are legal mechanisms which allow greater flexibility in managing water resources. A permit may allow additional water to be abstracted from a specified source or modify the conditions in an existing abstraction license. Drought Orders go further and can allow water companies to limit particular uses of water (e.g., bans on the use of hosepipes). In extreme drought conditions, Emergency Drought Orders allow particular categories of water use to be prohibited and the use of standpipes or water tanks to restrict public demand.

Operationally, much can be achieved by temporarily switching supply sources (e.g., by preferentially abstracting from groundwater or river abstractions to alleviate pressure on depleted reservoir stocks, increasing regional, or local, transfers of water to augment supplies in drought afflicted areas) or by reducing main pressures to limit leakage losses.

The robust statutory framework, together with increased regional and local inter-linkages between supply sources and scientifically based improvements in water

and environmental management, has helped to ensure that the deployment of standpipes and water tanks (in response to drought conditions) has not been needed since the end of the 1976 drought.

Climate change

The cluster of drought episodes over the 1990–2010 period heightened concern among the public and policy-makers that runoff variability and drought frequency may increase in a warmer world. In a period of actual, or anticipated, climatic change the management of water resources and the protection of the aquatic environment during periods of drought stress, present considerable challenges. Historically, water management strategies in the UK, as elsewhere, have been predicated on an assumption that rainfall and runoff variability occurred around a relatively stable long-term mean. This is an inadequate policy foundation in the face of anthropogenic climate change. Most climate change scenarios indicate that a warmer UK will also have higher potential evaporation demands, wetter winters, and drier summers (UKCP09, 2009). However, the uncertainty bands are wide, particularly in relation to how increasing temperatures will impact on rates of runoff and recharge – the critical factors in relation to water resources stress – across the wide range of catchment types encountered in England and Wales. It is essential therefore to maintain and improve observational monitoring programs to identify and quantify trends and, over time, to establish a fuller reconciliation between climate change scenarios and observational evidence; this is a necessary prerequisite for future policy development.

Droughts and Water Management in England and Wales: With Particular Reference to Reservoirs and Lakes, Figure 4 Estimated annual mean outflows ($\text{m}^3 \text{s}^{-1}$) for England and Wales (gray trace), 1961–2010.

Temperatures in England and Wales have increased by 1.2°C over the last 50 years, a very rapid rise in a historical context. This impacts directly on open-water evaporation rates and has implications for the frequency with which shallow water bodies (village ponds for example) dry up. Of more direct water resources interest are changes in rainfall, runoff, and aquifer recharge. Any significant reductions would be of concern especially across many southern areas where available resources are already heavily committed. Changes in the seasonality of rainfall could also have wide implications, particularly for smaller reservoirs. A combination of lower spring rainfall and increased evaporation rates could lead to steeper declines in reservoir stocks with potentially increased water supply stress during the late summer and autumn – before the seasonal recovery in runoff rates allows stocks to be replenished.

In contrast to temperature, observational evidence of recent trends in rainfall and runoff is much less compelling. There is no trend in annual mean precipitation totals over the 236-year national rainfall series (Jenkins et al., 2008) and, while some modest regional tendencies in runoff have been identified over time spans of 40 or more years (Hannaford and Harvey, 2010; Hannaford and Marsh, 2006), analyses of total outflows at the national scale suggest a long-term stability in runoff rates, albeit with substantial temporal variability. Figure 4 shows annual mean outflows for England and Wales based on fixed networks of gauging stations measuring outflows from major river basins. The variability between, and within, the five decades is considerable but there is no indication of any sustained decline in runoff. Indeed, the possibility that a tendency for a greater proportion of the overall rainfall to occur in the winter half year (October–March) may be reflected in the slight tendency for runoff to increase over the post-1960 period.

Indexing the direction, pace, and magnitude of any temperature-driven changes in runoff is the key to effective drought management in the future but any such changes

will be superimposed on natural climatic variability. Rainfall series extending back almost 250 years in England and Wales confirm that substantial seasonal changes have occurred. Most notably, winters in the nineteenth century tended to be drier than summers and clusters of dry winters were common. Over the 1890–1910 period, some southern regions registered only two or three wet winters and any modern repetition of this “Long Drought” (Marsh et al., 2007) would represent a real water resources challenge given contemporary water demands and environmental imperatives. A greater understanding of the mechanisms that influence multi-year and multi-decadal variations in drought frequency would allow drought mitigation strategies to be honed more effectively – adapting to periods when the probability of sustained rainfall deficiencies is increased.

Summary

Advances in the exploitation and management of water resources in England and Wales over the last 50 years have provided a substantial measure of resilience to all but the most extreme drought conditions. As yet there is little evidence to indicate that runoff at the national scale has decreased due to global warming and a modest tendency toward wetter winters would, if continued, have significant water resources benefits. However, the impact of both climate change and climate variability needs to be considered alongside projections of increases in population, domestic and agricultural water demand, and the priority afforded to the protection of the aquatic environment. This implies the need for a continuing review of drought mitigation strategies informed by rigorous methodologies to identify and quantify observational changes in runoff patterns across the country.

E

ECOLOGICAL THREAT TO LAKES AND RESERVOIRS

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Definition

Lakes and reservoirs hold about 90% of the world's fresh surface water. According to the discussions at the 9th International Conference on the Conservation and Management of Lakes held in Shiga, Japan, in 2001, warning was given of some one billion people being at risk from overuse, water withdrawals, and pollution of these water bodies. Similar warnings were given at the 3rd World Water Forum at the Kyoto Conference in 2003.

The principal threats worldwide appear to be:

- Accelerated eutrophication, which affects 54% of the lakes in the Asia-Pacific region, 53% in Europe, 28% of those in North America, and 41% of those in South America
- Chemical pollution, which is the second most commonly cited threat to lakes
- Alien plant and animal species, either introduced into lake environments in the ballast water of ships, as part of the aquarium trade, from small boats traveling between lakes, or in bait and by escaping from aquaculture, with some intentionally introduced to boost fishery production or to control another exotic species
- Acidification, which is a serious problem in most of central and northern Europe, the northeastern United States and southeastern Canada, Australia, New Zealand, Japan, and China, with many lakes in Scandinavia and the affected regions of North America becoming so acidic in the past few decades that they can no longer sustain the diverse forms of life originally found there

- Water withdrawals, which have risen to 3,800 cubic kilometers per year, one study estimating a sixfold increase in water withdrawals from lakes and rivers between 1990 and 1995

In industrialized countries, shallow lakes are the most endangered, especially those situated in areas of intensive agriculture or which have been depleted for drinking water and industrial uses. Those that are most at risk include the US' second largest lake, Lake Okeechobee, which has an average depth of just 10 ft (3 m); Arre Lake in Denmark; Hungary's Lake Balaton; the Aral Sea between Kazakhstan and Uzbekistan, which has dropped in area from the world's fourth largest lake to the eighth largest; and the world's deepest lake, Russia's Lake Baikal, containing about one fifth of the world's fresh surface water, facing pollution from industrial plants.

In the developing world, some of the most threatened lakes include Africa's largest, Lake Victoria and Lake Chad which has been reduced to one twentieth its size in four decades, and Taihu Lake in China because of severe pollution.

Once a lake becomes degraded, it takes a considerable time and a great deal of effort to restore it to health, and, as a consequence, successful restorations are rare, particularly in the case of large lakes. One success story is Lake Washington near the US city of Seattle, which was highly eutrophic until the 1970s, but was restored by installing a wastewater treatment system and diverting the treated effluent out of the lake's watershed. Managing lakes is difficult, not only entailing resolving important technological, financial, and institutional issues but also requiring support from industry and the public as well as government. A participatory, watershed-based approach is much more difficult to achieve for lakes in developing countries, where political instability and the lack of financial resources may be more common.

ENGLISH LAKES

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Introduction

The Lake District of England is not only famous for being one of England's prime tourist resorts but also its lakes being the subject of significant scientific study over the past 100 years. A considerable input to this scientific study has been undertaken since 1931 by the Freshwater Biological Association (FBA) and the Institute of Freshwater Ecology (IFE).

There are some 88 lakes and tarns (small lakes) in the group of lakes in the district of north east England.

It is interesting to note that only one of these lakes is known as a "lake" the one being Bassenthwaite Lake, all the others being tarns as in Blelham Tarn, or "mere" as in Windermere or with "water" in the name as in Ullswater.

Geology

The geology of the Lake District is complex with Skiddaw Slsate and Borrowdale Volcanic rocks formed some 500 million years ago. A system of radiating U shaped valleys formed by glaciation some 15,000 years ago subsequently filled with the lakes we see today. On three sides there is a rim of carboniferous limestone.

The area of the Lake District is about 2,300 km² with a width from east to west of 55 km.

Ecology

The physical, chemical, and biological characteristics of the 15 most important lakes are given in [Tables 1–3](#) from J.F.Talling ed. published with permission of the Director of the Freshwater Biological Association, Windermere, Cumbria, UK.

Retention time

The mean retention time of a lake is an important characteristic especially if water has to be extracted from the lake. Mean retention time, RT, is

$$RT = V \div I$$

where V is the lake volume and I is inflow rate, the latter being the amount of rainfall plus streamflow. For an approximate solution to the equation for the Lake District,

English Lakes, Table 1 The Cumbrin lake series: geographical and physical features of major lakes arranged in order of increasing productivity, estimated from mean chlorophyll-*a* concentrations in 1991. R, NB and SB as in Table 1

Table published with permission of the Director FBA

the average lake catchment rainfall may be taken as 2,500 mm per annum and average runoff factor 0.75. The retention time in days is then

$$RT = (V \div A) \times 195$$

where V is in 10⁶ m³ and A is in km².

The complete calculation is performed by hydrological survey where the values for rainfall and inflow and out-flow values can be estimated by hydrological survey. In Table 1, the values for Windermere and Bassenthwaite

Lake have been calculated as 266 days and 23 days respectively as follows:

$$\text{Windermere: } RT = (314.5 \div 230.5) \times 195 = 266 \text{ days}$$

$$\text{Bassenthwaite } RT = (27.9 \div 237.9) \times 195 = 23 \text{ days}$$

Seasonal and long-term change

Individual lakes experience similar seasonal change but vary individual in long-term change. Weather has led to varying rates of sediment deposits in different lakes with high rates since the postglacial period (Figure 1).

English Lakes, Figure 1 The English Lake District, showing the drainage relationships of the lakes.

Sewage purification is of a high standard especially the effluent into Windermere where the removal of phosphate has had improved effect.

Seasonal changes, apart from varying vertical stratification, is expressed in annual cycles of nutrient concentrations and plankton.

Water balance

The hydrological water balance for Windermere has been developed for the period 1939 to 1984, for example, as follows:

Runoff $431 \times 10^6 \text{ m}^3$ per annum ranging from 110 to $689 \times 10^6 \text{ m}^3$ per annum

Total lake volume = 314.5×10^6 giving a mean retention time of approximately 9 months.

The range of water level is about 2 m and water is abstracted from the lake to the Manchester aqueduct.

Density stratification

Each lake experiences a temperature density layering during summer with differentiation into an upper epilimnion, an intermediate metalimnion with thermocline and a lower cold hypolimnion. The temperatures are lowest in January and February and the thermal stratification in April and May but may change slightly dependent on the Atlantic Gulf Stream.

Dissolved gases (O_2 CO_2 and pH)

Large season changes are found in oxygen and carbon dioxide. The changes in carbon dioxide affect chemical species are related to pH values. The largest concentrations are in the epilimnion, oxygen by phytoplankton photosynthesis, carbon dioxide by respiration and decomposition. Those of oxygen occur with yearly variation either in the metalimnetic (thermocline region) or in the late summer or autumn hypolimnion.

Plant nutrients

Season and annual changes in concentration of plant nutrient elements such as carbon, silicon, phosphorous, and nitrogen are carefully monitored. Any depletion of these elements may result from phases of algal growth especially in summer but least in winter. Estimates have been made of the annual input of phosphorous using river and sewage work flows and population. The estimated annual loading in the 1980s is about 1.72 g P per m^2 .

Heavy metals

Values of concentrations of zinc, lead, copper, cadmium, and mercury in the lake are low being less than $3 \mu\text{g per l}$. Sediments deposited during the last 130 years are enriched in the heavy metals. Rates of deposition have been measured directly in sediment traps.

Bacteria

Counts of bacterial concentrations are relatively recent but concentrations of the fecal *Escherichia coli* and

streptococci have been higher in areas where contamination by incompletely treated sewage (stormwater overflows) was still a problem although the small sewage works on the Windermere now produces an excellent effluent.

Algae

Blue-green algae in the lakes begin increasing in spring and peaking in summer depending on the cellular variable proportions of phosphorous which when low is an indicating limiting factor for growth.

Bottom-living algae (benthic) occur attached or free on various substrata in littoral areas that receive enough illumination.

Benthic bottom-living invertebrates are broadly differentiated with depth into littoral, or sublittoral. Several have spread widely around the lakes. The sublittoral community was surveyed in Windermere in 1934–1935.

Macrophytes and zooplankton

Macrophytes grow in a depth-range of the littoral with sufficient illumination in bays and shallows protected from wave effect and sediment. Surveys since 1913 in Ullswater have recorded flora of 20 submerged microphytes. Zooplankton community is important for food for young fish and surveys have shown a widely distributed specious in all Cumbrian lakes. Surveys in 1921 in Ullswater have recorded a widely distributed specious.

Fishes and water birds

A total of some 18 species of fishes are found in the lakes including brown trout, arctic char, perch and pike according to surveys carried out since 1940. Changes of poth perch and pike have been reported influenced by human removals or predation.

The wildfowl population has been monitored since 1967 which showed that the highest total counts are obtained in the winter months and for four species of duck since 1978 averaging a total of 2,647 in Windermere alone, coot adding a further 1,168 birds. For the goldeneye Windermere is a site of national importance with over 200 birds recorded in.

In 1970–1975 the lakes annual population of growing ducklings was estimated to consume some 2.6 t of fish per year. There is also some consumption by cormorant and heron. Recreation use of the lakes has had an effect on the bird conservation in both summer and winter.

Introduction

The word estuary is of sixteenth century origin and originated from the Latin *aestuarium*, which means marsh or channel, and this is derived from the Latin *aestus*, meaning tide or billowing movement. Estuaries are transitioning environments between the land and the

ocean, where fresh water coming from the rivers mixes with saline oceanic water. This river inflow need not be perennial. There are several definitions of estuaries. For freshwater scientists the main thing is to define the head of an estuary; in one definition, this is the salinity limit; in another definition, this is the tidal limit; and in still another definition, it is the source of the fluvial sediment. For coastal scientists and oceanographers, the mouth of an estuary, i.e., the point where an estuary ends, is also ill-defined. It can be a geographic feature or the seaward edge of a tidal plume in the open ocean.

Whatever the geographical definition, an estuary is a zone of transition with gradients in salinity, sediment characteristics, turbidity of the water column, chemical composition including nutrients, dissolved gases, and trace metals and in diversity and productivity of species of animals and plants. Estuarine waters are commonly more biologically productive than the oceanic waters. In addition, estuaries are strategic locations for human development; nearly 69% of the largest cities in the world are located on river estuaries. The scientific understanding of estuaries is thus of great practical importance.

An estuary is never at a steady state. Its bathymetry is continuously evolving. Forced by tides, waves, and river inflows, estuarine water is continuously moving and with it, its ecology is also continuously evolving. Some largest estuaries may have the additional direct influence of winds on the local circulation such as the Amazon River. The resulting physical and biological features of an estuary and its ecosystem health are determined by the time scales of the processes controlling the movements of water and sediments and the ecological processes in the water and on the bottom.

Genesis and geomorphologic time scales

The physical features of an estuary are determined firstly in a time scale of centuries from the recovery of the global mean sea level (MSL) from the last glaciation (i.e., eustatic variation) and the tectonic movements that resulted (i.e., isostatic variation), and secondly in a shorter time scale from human-induced changes in river discharge Q_r and riverine sediment inflow Q_s . Global MSL was 120–130 m lower 20,000 years ago than at present (Figure 1a). The melting of the ice resulted in a rebound of the continental plates relieved of the pressure of ice glaciers. As a result the relative MSL varied spatially in three zones (Figure 1b) of, respectively, ongoing decrease, relative stability, and ongoing small increase (Figure 1c). The global MSL has been fairly constant for the last 6,000 years. It is now at a high stand level that was last reached about 120,000 years ago. Old river and flood plains became flooded by rising seas; estuaries were formed as they filled with sediment originating from the watershed and from the sea; watershed sediments were brought in by rivers and coastal sediments were brought in by tides and storms.

Estuarine Hydrology, Figure 1 (a) Time series plot of the global mean seal level over the last 140,000 years. (b) The approximate distribution of the coasts that followed one of the three typical relative mean sea level curve types A, B, and C as shown in (c) (Redrawn from Wolanski et al. (2009)).

Thus most estuaries have not reached a steady state yet; they are still evolving. They have an age; they all started young, many have reached maturity though not the fjords, and some have reached old age, which means that they cannot accommodate any additional sediment. The extra sediment is carried seaward to be dispersed at sea or to form a delta. An old estuary can be rejuvenated when a major river flood creates a new river mouth.

As sketched in Figure 2, the infilling of an estuary of volume V is controlled by the inflow of riverine sediment $Q_{s,in}$, the net balance ΔQ_s between seaward ocean flux $Q_{s,out}$ and the landward sediment flux from coastal water $Q_{s,in}$, and the sediment flux to lateral storage in the flood plains $Q_{s,storage}$. The geomorphologic age of an estuary is the time it takes for the net sediment flux to fill the volume V . The aging of an estuary can be greatly accelerated by human activities in the watershed, mainly land clearing. As an example this geomorphologic age T was estimated for a number of macro-tidal muddy estuaries in the Pacific region (Figure 3); T varies between several thousand years for estuaries that are non-impacted by human activities (rank 1), to several hundreds of years for estuaries that are moderately impacted by land clearing in the watersheds (rank 2), to only several tens of years for estuaries

Estuarine Hydrology, Figure 2 A sketch of the net sediment budget in an estuary.

that are severely impacted by land clearing in the watersheds (rank 3), illustrating the rapid acceleration of the aging of estuaries by siltation due to land clearing in the watersheds.

Dams on the other hand can trap sediment in reservoirs and thus prevent sediment to reach the estuary, which

Estuarine Hydrology, Figure 3 The geomorphologic age of macro-tidal, muddy estuaries in the Pacific.

Estuarine Hydrology, Figure 4 A sketch of the sediment budget in the micro-tidal Nile and Colorado deltas (*left*) before and (*right*) after dam construction.

slows down the estuarine aging process. This is particularly the case for micro-tidal and tideless estuaries. Before the mega-dam was constructed some riverine sediment was trapped in the estuary that usually comprised a lagoon and a delta; the rest was exported to the sea (Figure 4a). The mega-dams in the Colorado and the Nile rivers have stopped all (most) river floods' export of water and sediment to the sea (Figure 4b) and significantly decreased the inflow of sediment to the estuary. The

channels are silting slower, i.e., aging slower, than before due to lesser sediment inflow from the dam, while the coast is eroding.

However, in macro-tidal estuaries, large dams can accelerate the aging of estuaries. This is because they can decrease or even stop large river floods; this prevents seaward flushing of estuarine sediment and accelerates tidal pumping of coastal sediment landward into the estuary; these result in siltation and thus aging the estuary.

At the same time however the coast becomes starved of sediments, which are exported by waves and currents in the open sea; as a result, the coast erodes.

Sediment dynamics time scales

Estuarine sediments are of two types: cohesive sediments (also called mud or clay) have a mean particle size $d_{50} < 4 \mu\text{m}$; non-cohesive sediments (sand) have a $d_{50} > 64 \mu\text{m}$. Silt has a d_{50} in between those of mud and sand; it is weakly cohesive.

The sediment dynamics depend on the currents, the salinity, the type of sediment, and the biology. Sand is mainly carried along the bottom and very close to the bottom. Mud is mainly carried in suspension within the water column.

There are several models, pioneered by engineers, to calculate the sand transport as bed load. The models generally assume either that the sand moves as a creeping movement of layers along the bottom or that the sand particles are rolled and tossed over the bottom in a process called saltation. The models are based on laboratory studies and estimate the bed load transport as a function of the mean particle size d_{50} , the current-induced stress, a threshold stress for bed load to commence, and the difference in density between the water and the sediment. They yield at best order-of-magnitude estimates and thus must be used with caution. Sand is often mixed with mud and even if the sand is the dominant fraction, the clay particles modify the bed load by a factor of 2–4.

Cohesive sediment (mud) behaves differently than non-cohesive sediment (sand) because it forms flocs typically 100–200 μm in size. Flocculation is initiated by salinity ions that cause electronic forces between the small sediment particles and greatly enhanced by the bacteria and plankton that, through the production of transparent

exopolymer particles (i.e., a mucus), aggregate flocs to form extremely large flocs (commonly 1,000 μm in size) and are called marine snow flocs. In very turbid waters ($\text{SSC} > 500 \text{ mg L}^{-1}$), marine snow is scarce; in less turbid waters (typically $\text{SSC} < 100 \text{ mg L}^{-1}$), marine snow is common. The biology also controls the erodibility of the bottom sediment because algae mats stabilize the bottom sediment and animal burrows may loosen the sediment and facilitate erosion. There are models, pioneered by engineers, to calculate the mud transport as a suspended load. They are largely based on laboratory experiments and they generally fail in the field because the laboratory experiments cannot account for the biology in the field.

The vertical profile of suspended sediment concentration (SSC) takes many shapes, from vertically nearly well-mixed (line a in Figure 5), to smoothly increasing with depth (line b), to a step structure called the lutocline for $\text{SSC} > 5 \text{ kg m}^{-3}$ (line c). Because the suspended sediment increases the density of the water, the water density changes across the lutocline. This reduces the vertical diffusion coefficient K_z in the lutocline, in the same manner that a thermocline inhibits vertical mixing between the hypolimnion and the epilimnion. This helps preserve a fluid mud layer near the bottom.

Riverine mud in suspension commonly reaches the estuary unflocculated. On reaching the estuary, this mud flocculates as a result of the action of salinity and the biology (Figure 6a). Salinity-driven currents, tidal currents, and weaker cohesive forces of silt flocs as opposed to mud flocs generate a physical filter that sorts the silt from the clay (Figure 5a) and that creates a turbidity maximum zone (Figure 5b). Marine muddy snow forms a biological filter that inhibits the export of mud from estuaries (Figure 6c). Finally the riverine mud mixes with, and is diluted by, the estuarine mud through erosion and

Estuarine Hydrology, Figure 5 Three typical vertical profiles of suspended sediment concentration in estuaries.

Estuarine Hydrology, Figure 6 (a) The physical filter of fine sediment that generates (b) a turbidity maximum zone, i.e., a zone with the highest suspended sediment concentration (SSC); the SSC curve varies with the tides. (c) Biologically produced transparent exopolymer particles and fine sediment in suspension interact to produce muddy marine snow flocs that accelerate the settling of the mud and generate a biological filter inhibiting the export of fine sediment seaward. (d) Riverine mud is diluted by estuarine mud.

sedimentation as a result of floods, waves, tides, and storms (Figure 6d). In some estuaries, the tidal currents are larger during the rising tide than during the falling tide; in those estuaries, the tides pump the sediment landward. These processes greatly increase the residence time in the estuary of the riverine mud and its particulate pollutants and nutrients.

If the estuary is sandy, the sediment is also trapped in the estuary and the trap is also leaky, with sediment imported both from the sea and from the rivers and exported offshore during large river floods. The evolution of a sandy estuary geomorphology is difficult to predict because of the difficulties in measuring sandy sediment fluxes. Observations suggest that the dominant forcing functions controlling the movement and trapping on sandy sediments in estuaries are the oceanography (tidal dynamics and storms) and the hydrology (floods).

Classification based on geomorphology and on water circulation

Estuaries may be classified upon their geomorphology or physical oceanography.

The estuarine types based on the geomorphology are mainly (1) drowned river valleys, (2) lagoon-type or bar-built, (3) fjords. Most of the drowned river valleys were formed with the sea level rise on low and wide coastal plains (e.g., Chesapeake Bay, Tampa Bay, and Delaware Bay). The lagoon types are semi-isolated from coastal waters by barrier beaches and some lagoons are extremely large (e.g., Lagoa dos Patos in Brazil that is 242-km long, and the Mirim Lagoon in the border between Brazil and Uruguay that is 290-km long, and the well-known Venice Lagoon, famous in human history). These estuaries have only a few narrow inlets allowing the interaction between the estuary and the coastal zone. The fjords were formed in

Estuarine Hydrology, Figure 7 Classification of estuaries based on the physical oceanography.

deeply eroded valleys caused by the glaciers; many of them have shallow areas near the estuarine mouth, and thus restricting the water flow. Fjords often have lower temperatures than coastal waters (e.g., the deepest fjord is the Sognefjord in Norway with depths up to 1,300 m, and the largest fjord is Scoresby Sund in Greenland that is 110 km long).

The classification based on the estuarine circulation is based on the vertical distribution of salinity in the estuary, and the types are (1) salt wedge, (2) partially mixed, (3) well-mixed, (4) fjord-type, and (5) salt plug (Figure 7). In salt wedge and fjord-type estuaries, the river inflow greatly exceeds tidal currents, freshwater moves as a distinct surface layer, and a sharp salinity interface separates the fresh/brackish water on top from the saline water underneath. In partially mixed estuaries, the tidal currents only slightly exceed river inflow, and thus cause more vertical mixing, which reduces vertical salinity gradients. Well-mixed estuaries are dominated by tidal mixing, thus the vertical salinity stratification is negligible. Salt plug estuaries occur in the dry climates, where evaporation greatly exceeds river inflow, resulting in higher salinity in the estuary than at the mouth.

Biological implications of sediment transport

At high SSC (highly turbid), there is nearly complete darkness. Typically, for suspended sediment concentration (SSC) = 0.2 g L^{-1} , visibility < 30 cm; for SSC = 1 g L^{-1} , visibility < 1 cm. The plankton in these turbid waters can only photosynthesize for the short time that it is brought to the surface by turbulence. The benthos has no such opportunity; it stays in complete darkness as long as the water stays turbid. In addition, even in the absence of suspended sediments, light is attenuated with depth depending on the plankton (shading effect) and on dissolved organic matter (DOM).

Mud also affects pollutants (such as PCBs and heavy metals) and nutrients (particularly phosphorus, less so for nitrogen) because these particles are readily absorbed

on the mud due to the electric and colloidal forces on the clay particles. Thus pollutants can stay trapped hundreds of years on settled mud and are released when the mud is resuspended. Suspended mud is important in absorbing dissolved nutrients and largely making it unavailable by the plankton. This is quantified by the partition coefficient K_d

$$K_d = \text{mass absorbed on particulates} / \text{Total mass} \quad (1)$$

and this was quantified by Middelburg and Herman for estuaries in Europe; they found at suspended particulate matter (SPM) of 10 mg L^{-1} about 10% of the organic carbon may be present in particulate form, and this was about 50% at SPM of 100 mg L^{-1} and 80% at SPM of 400 mg L^{-1} . Phosphorus is also readily absorbed on suspended mud and nitrogen less so. Thus, in muddy estuaries, the classical stoichiometry ratios for dissolved inorganic nutrients C:N:P = 106:16:1 may not hold, and this invalidates the use of aquatic ecosystem models based on stoichiometry.

In muddy estuaries, most heavy metals and a number of pollutants such as PCBs and POPs are nearly totally sequestered on mud particles; they are thus extremely slowly flushed out of polluted, muddy estuaries, and are thus a legacy of pollution that may last many decades, and even centuries, after the pollution source was stopped. This is the case for instance of Boston Harbour in the USA and the Elbe Estuary in Germany.

The impact of riverine nutrients on an estuary is very different for a sandy (clear water) estuary where the nutrient is readily bioavailable and light penetration allows photosynthesis, than for a muddy (turbid) estuary where much of the nutrient, especially phosphorus, is absorbed on the mud and photosynthesis is inhibited by the lack of light.

Tidal wetlands

The vegetation in tidal wetlands plays an important role in controlling the net sediment flux in or out of an estuary.

These wetlands were originally non-vegetated intra-tidal mudflats exposed at low tide and inundated at high tide. These mudflats commonly have a tidal creek that focuses the largest currents in the creek; the currents remain small in the surrounding flats where sediment can thus accumulate. These non-vegetated mudflats are often unstable and are readily modified by storms. All this changes drastically when the sediment accumulation results in the substrate rising above mean sea level. At that stage the vegetation establishes itself, consisting typically of salt marsh plants in temperate climate and mangroves in tropical climates. Through its roots below ground the vegetation helps stabilize the tidal creek; through its structure above ground the vegetation accelerates sedimentation by slowing down the water and thus enabling the suspended sediment entering the intertidal areas at rising tide to deposit. The difference between the sediment that comes in at rising tide and the sediment that goes out at falling tide is the sediment trapped in the tidal wetlands. This role of vegetation is crucial in enhancing sediment trapping in estuaries; for instance a mangrove that covers 3.8% of the river drainage area traps 40% of the riverine mud inflow; a salt marsh where plant height exceeds 8 cm may enable sedimentation at a rate of up to 8.2 cm year⁻¹; the rate of sedimentation of British salt marshes averages 4.3 mm year⁻¹ and a similar result is also found in US salt marshes. Storms may disturb this trend in the short-term.

Tidal wetlands comprise globally mainly mangroves and salt marshes. Mangroves worldwide cover an area of about 240,000 km² and are the dominant coastal wetland in subtropical and tropical regions where frosts do not occur. Salt marshes are distributed worldwide, mainly in areas subject to frosts where mangroves do not grow and in the higher grounds next to mangroves; thus they are most common in middle and high latitudes; their vegetation comprises mainly salt-tolerant grasses and rushes. Mangroves and salt marshes vegetation exhibit zonation patterns whereby the vegetation is the thinnest in the areas of lowest elevation where sediment accretion occurs. A mild slope in the vegetated wetlands forms a drainage pattern toward the tidal creek.

The importance of tidal wetlands to the estuarine ecosystem is not limited to sequestering nutrients and pollutants. Tidal wetland vegetation converts excess nutrients in the flowing waters into plant biomass; in turn this plant biomass supports an ecosystem. Organic detritus such as plant litter is exported from the wetlands to the estuary. The wetlands also provide a nursery for fish and crustaceans that come in from the estuary – and the sea for migrating species – to feed and shelter within the salt marsh and later return to the estuary or the sea; this forms an important exchange of organic nutrients between the tidal wetlands on the one hand and estuarine and coastal waters on the other hand. The nutrient outwelled from tidal wetlands increases the estuarine plankton community, which in turn supports commercial fisheries of fish and shrimps, the success of which is closely linked to tidal wetlands.

The water transport time scales

The movement of water in an estuary is controlled by the tides, the river inflow, rainfall and evaporation, the wind, and events at sea such as storms. The multitude and variety of these factors, their interaction with the often shallow and highly irregular bathymetry, contribute to a complex nonlinear and unsteady three-dimensional hydrodynamics.

Models of varying complexity can be used order to describe and quantify the transport of pollutants and the renewal of water.

Box models, in particular, are often used for a quick assessment of the flushing capability of an estuary. In the simplest approach, the estuary is modeled as a single box. Assuming steady state, the turnover time or flushing time T of the estuary can then be estimated as

$$T = V/Q \quad (2)$$

where V is the water volume in the estuary and Q is the total freshwater input. In tidal estuaries, the amount of water exchanged at each tidal cycle is estimated as the difference of water volume between high and low tides, the so-called tidal prism V_p (Figure 8a). Using this tidal prism flushing model, a fraction

$$r = V_p/V \quad (3)$$

of the estuary water is assumed to be renewed by ocean water at each tidal cycle and the turnover/flushing time can be expressed as

$$T = \tau/r \quad (4)$$

where τ is the tidal period (e.g., 0.5 day for solar semi-diurnal tide and 1 day for solar diurnal tide).

The above models provide a very crude description of the exchange processes between the estuary and the coastal sea region. Very often, the net water exchange results from the difference between two opposite water fluxes corresponding to the inflowing sea water and the outflowing estuarine water. In the gravitational circulation model (Figure 8b), these water fluxes are associated with the two-layer baroclinic circulation typical of partially mixed estuaries (Figure 7). In well-mixed broad estuaries, the two opposite fluxes can occur simultaneously in the horizontal plane (Figure 8c).

Using the configuration of the LOICZ model shown in Figure 8c, the steady-state water balance in the estuary requires that the outflowing flux be the sum of the freshwater input in the estuary Q_r and the seawater inflow Q_d . Expression (Eq. 2) of the turnover time can then be generalized with $Q = Q_r + Q_d$.

As steady state, the rate Q_d can be calculated from the salt balance

$$Q_d \Delta S = Q_r S_{out} \quad (5)$$

where S_{out} is the salinity of the estuarine outflow and ΔS is the excess salinity brought by the seawater, i.e.,

Estuarine Hydrology, Figure 8 (a) The tidal prism box model (*side view*); (b) the gravitational circulation box model (*side view*); (c) the LOICZ box model for a vertically well-mixed estuary (*plan view*).

$$\Delta S = S_o - S_e \quad (6)$$

where S_o is the salinity in coastal waters and S_e is the estuarine salinity. Setting $S_{out} = S_e$ leads to the

$$T_r = V / Q_r (1 - S_e / S_o) \quad (7)$$

The LOICZ method for the derivation of the renewal time is similar but S_{out} is taken as the mean salinity in the outer estuary, which is estimated as

$$S_{out} = 0.5 (S_o + S_e) \quad (8)$$

The LOICZ box model is simple and easy to use and has been used in about 200 estuaries worldwide. Rainfall, groundwater, and evaporation can also be added if needed. If the system is not vertically well-mixed, a stacked box model can be used with a box on top representing the upper layer and a box on the bottom representing the lower layer and the vertical fluxes are calculated from salinity data.

The above box models, which can be further refined, are useful as a first approach but have serious limitations because they only capture some of the physics (e.g., Sheldon and Alber, 2006). They are all based on a steady-state balance, assume complete and immediate mixing in the estuary, poorly account for the diffusive fluxes between the estuary and the coastal sea, and ignore the spatial variations inside the estuary.

The flushing rate and the transport of pollutants also depend on the internal circulation within the estuary driven by the density difference generated by changes in salinity and temperature. This difference in density is determined by vertical mixing by the wind, by boundary-generated turbulence, and by turbulence in the water currents driven by tides, wind, and river inflow. Vertical mixing is parameterized by the vertical eddy diffusion coefficient K_z , which is minimal at the level of the density interface (i.e., the pycnocline). Additional mixing also results from turbulence generated at the banks of the

Estuarine Hydrology, Figure 9 Path followed by a particle in the estuary from the upstream boundary to the coastal sea. At time t , the age of the particle is $t-t_0$, its residence time is t_1-t , its transit time is (t_1-t_0) , its exposure time is $(t_1-t) + (t_3-t_2)$.

estuary and by secondary flows around shoals and islands, as well as three-dimensional flows in meanders.

A proper description of estuarine dynamics and the assessment of the associated transport rates require therefore two-dimensional (either in the horizontal or in the vertical plane) or even three-dimensional models. Such models are elegant but they still carry uncertainties in term of the hydrodynamic conditions and the fate of tracers at the open boundaries as well as in quantifying the turbulent diffusion. Also the influence of small scale features and the possible occurrence of sandbanks that fall dry at low tide require special numerical treatments. Unstructured grid models permitting local refinements of the computational mesh where necessary and taking into account external influences in a natural way are particularly suited for such studies (de Brauwere et al., 2011).

The refined description of the water circulation provided by high-resolution numerical models gives also access to more representative transport timescales, namely, the age, the residence time, the exposure time,

and the transit time, superseding the poorly defined flushing time, turnover time, and renewal time. These timescales are best introduced by considering the fate of a water parcel or of a tracer particle (Figure 9).

The age of a particle measures the time elapsed since it entered the estuary. The age reflects therefore the past history of the particle. With the residence time, one looks forward in time: The residence time is time necessary for a water parcel originally in the estuary to leave the domain for the first time. The exposure time is similar to the residence time but allows for particles to return into the estuary after leaving it (with reversing tidal currents, for instance); the exposure time of a particle originally in the estuary is the total time that the particle will spend in the estuary. The transit time of a particle is defined as the sum of the age and the residence time (Takeoka, 1984; Zimmerman, 1988).

Because of mixing, different particles introduced in the estuary at exactly the same location and at the same time will follow different trajectories and are therefore characterized by different timescales. Distributions of age, residence time, exposure time, and transit time must therefore be considered, although one can usually content oneself with their average value in most cases.

The Constituent oriented Age and Residence time Theory (Delhez et al., 1999, 2004) provides the appropriate framework to compute the above timescales in an Eulerian framework, in a suitable form to be easily implemented in existing numerical models. The mean residence time ϑ , for instance, can be obtained as the solution of the advection-diffusion problem

$$\frac{\partial \vartheta}{\partial t} + 1 + \nabla \cdot (v\vartheta) + \nabla \cdot (K \cdot \nabla \vartheta) = 0 \quad (9)$$

(where t is the time, v is the velocity, and K is the diffusion tensor) with boundary conditions prescribing that ϑ vanishes at the open boundaries. To compute the exposure time, the same equation must be solved but the model domain must be extended offshore to describe the coastal circulation and describe the possible return path of tracers.

Exact analytical solutions are available if the estuarine cross-section is constant along the channel, which is often a restrictive assumption.

Table 1 compares transport timescales computed using different approaches in various estuaries. Large differences between the various time scales exist for the same estuary, highlighting the importance of defining precisely the particular time scale needed for particular applications.

When the estuary is density-stratified, the residence time of water in an estuary also depends on the internal circulation within the estuary driven by the density difference generated by changes in salinity, temperature, and suspended sediment concentration. This difference in density is determined by vertical mixing by the wind, by boundary-generated turbulence, and by turbulence in the water currents driven by tides, wind, and river inflow. Vertical mixing is parameterized by the vertical eddy diffusion coefficient, K_z , which is minimal at the level of the density interface (i.e., the pycnocline). Additional mixing also results from turbulence generated at the banks of the estuary and by secondary flows around shoals and islands, as well as three-dimensional flows in meanders.

When the bathymetry is complex, e.g., with meanders or shoals, the water circulation in estuaries also varies markedly across the width, forming regions of convergence (where floating matter accumulates) or divergence (where floating matter disperses swiftly). This also modifies the water transport time scales.

Ecological implications of the transport time scales

For a given estuary, the geomorphologic time scale determines the estuarine bathymetry. The habitats, including tidal wetlands and rocky zones, are determined by the underlying geology as well as the geomorphologic time and sediment transport time scales. The fate of nutrients and pollutants is determined by the habitats and the sediment and water transport time scales. In turn, all of these parameters determine the ecology of the estuary.

Estuarine Hydrology, Table 1 Example of the water transport times (in days) for various vertically fairly well-mixed estuaries

	Renewal time (LOICZ box model)	Average residence time (CART, 1D)	Average exposure time (CART, 1D)	Average residence time (numerical model)
Curimataú Estuary (Brazil)				
Neap tides	0.5–0.9	0.1–0.6	1.2–1.7	–
Spring tides	0.5–1.4	0.02–0.1	1.4–2.2	–
Hudson Estuary (USA)				
Neap tides	4.3–5.3	1.2–2.3	6.2–6.7	8–10

Conwy Estuary (UK)				
Neap tides	31.8–35.3	10.2–12.8	74.6–81.1	–
Spring tides	28.1–31.2	6.0–7.7	109.5–120	–
Mersey Estuary (UK)				
Typical flow range	3.5–7.8	0.5–1.7	35.4–99.5	1–6.3
Scheldt Estuary (Belgium, The Netherlands)				
Average conditions	23.8–75.2	5.3–10.4	204.1–302.5	5–70

In a vertically well-mixed estuary, the nutrient is cycled between phytoplankton and resuspended microphytobenthos, zooplankton, bivalves and crustacea, and fish (Figure 10). Dying organisms, excreta, and leftovers from messy eaters become detritus that is recycled, some through the microbial loop. As shown by the dotted lines, tidal wetlands provide detritus and juvenile fauna to the estuary. This ecosystem is not closed; in fact, it is supported by an inflow of nutrients, fish, and plankton from the sea and the watershed (the river and groundwater); some of that matter is also lost by export to the sea. The level of processing of these various inflows depends on a large number of parameters including the climate, the habitats, the intensity of the inflows, the water and sediment transport time scales, and the partitioning coefficient. In turn

the estuarine ecosystem is determined by these physico-chemical attributes and the ecological niches.

The same nutrient cycling may prevail in the top layer of a salt wedge estuary (Figure 11). However, the situation is very different in the bottom layer, which is enriched by organic matter falling down from the top layer especially if the top layer supports an algal or plankton bloom. This organic matter decays in the bottom layer and extracts dissolved oxygen from the water column. As the bottom layer is not in contact with the water surface and the salinity stratification completely shuts down the turbulence at the salinity interface, oxygen cannot be supplied from the top layer. Oxygen can only be supplied by ventilation, i.e., the import of oxygen by currents bringing in oceanic waters in the bottom layer. This bottom layer becomes

Estuarine Hydrology, Figure 10 (a) A typical pelagic food web in a vertically well-mixed estuary. It comprises a waterborne ecosystem (the blue box) that is moving with the water currents, thus comprising an inflow into the estuary and an outflow from the estuary; it is flushed at a rate determined by the water transport time scales. It comprises also suspended sediment that is also varying in time at a rate determined by the sediment transport time scales. It comprises also a benthos and bottom dwelling animals living in habitats that are varying in time at a rate determined by the geomorphologic time scale. (b) Typical salinity distribution increasing from the head to the mouth. The waterborne ecosystem (blue box) is advected seaward, thus remaining only in transient contact with the substrate and the tidal wetlands, and at the same time it is subject to increasing salinity as a result of mixing. As it moves toward the head of the estuary, the waterborne ecosystem also encounters different habitats.

Estuarine Hydrology, Figure 11 A sketch of the water circulation in a salt wedge estuary. Organic detritus settles from the top layer where it is produced by an algal/plankton bloom. By decaying in the bottom layer, this material extracts dissolved oxygen from the water column. Low dissolved oxygen commonly results in the bottom layer. If the inflow rate of dissolved oxygen by oceanic inflow in the bottom layer is smaller than the consumption rate of dissolved oxygen by the decay of organic matter in suspension and on the bottom, anoxia can result.

anoxic if the oxygen consumption rate is larger than the rate of import of oxygen from oceanic water.

Partially mixed estuaries may suffer less from bottom water anoxia than salt wedge estuaries because the salinity stratification is less intense and does not completely shut down the turbulence; some vertical mixing remains and as a result additional oxygen is provided to the bottom layer by vertical diffusion of oxygen from surface waters.

Each of these physicoecological relationships is affected by the human impact. A most common indicator of a severe human impact is that the bottom layer of vertically stratified estuaries – which has the largest water transport time scales – becomes anoxic or hypoxic. Estuaries with a small value of the water transport time scales have less time for the dissolved oxygen to be depleted and for sediments to accumulate in the estuary; such estuaries are thus intrinsically more robust than poorly flushed estuaries.

Another indicator of the human impact is the increasing frequency of harmful algae blooms. High riverine loads of nitrogen and phosphorus into an estuary initially lead to a bloom of phytoplankton or diatoms because their rate of uptake of nutrients is much larger than that by cyanobacteria. In nutrient-enriched estuaries located downstream of large dams that preferentially trap the fine sandy sediment, the phytoplankton or diatoms can exhaust the silicate but not nitrogen and phosphorus; when that happens, cyanobacteria take over and harmful algae blooms can result. This situation is becoming common in many estuaries worldwide with a large water transport time scale and a large input of nutrients from sewage and fertilizers.

EUROPE, LAKES REVIEW

Rhodes W. Fairbridge (Deceased), Lars Bengtsson¹
¹Department of Water Resources Engineering, Lund University, Lund, Sweden

Introduction

The continent, with offshore islands, including the Faeroes but not Iceland or Svalbard, covers 10,350,000 km². Its eastern border is taken as the Ural Mountains and Ural River. Its longest rivers are the Volga, Danube (Donau), Ural, Dnieper, Don, Pechora, Dniester, Dvina, and Rhine. Iceland (about 100,000 km²) is below included when presenting the European lakes. Europe's northern limit is North Cape (Norway) at 71°10'20"N. and its southern limit is Cape Tarifa (Spain) at 36°01'N, although the southern point of Cyprus (34°30'N) exceeds this. The western limit of the mainland is Cape Roca (Portugal, at 9°30'W); when Ireland is included it is Dunmore Head (Eire, at 10°30'W). The eastern limit is in the farthest north of the Ural mountains (75°30'N).

Europe has some very famous lakes, treasured as beauty spots and honored in song and literature, although most of them are rather small. The majority are associated with the glacial history and deglaciation of the great Fennoscandian ice sheet, and the smaller ones with the glaciers of the Alpine area and the British Isles. Numbers of the lakes have had a compound history: beginning as structural features that were often initiated by strike-slip faulting in the Caledonian or Hercynian orogenies, but later modified by Quaternary glacial activity (e.g., Loch Ness).

Two very large water bodies with many lacustrine characteristics, in this volume are treated as “lakes,” although usually classified as “seas,” are the Black Sea and the Caspian. The latter is bisected by the Europe–Asia boundary, and is treated in the review under “Asia.” In the paleogeographic history of southern Europe and the Mediterranean, the name “Tethys” is intimately associated. It was originally a proto-Mediterranean seaway that divided much of the Earth's continental areas (Gondwanaland and Eurasia) for at least the last 150 million years. The Eurasian landmass to the north, and the African-Arabian-Indian blocks to the south. As these two moved apart, Tethys widened. As they approached briefly from time to time, twin orogenic belts developed parallel to the receding margins. The Viennese professor Leo Kober called this duality the “Zweiseitigkeit der Orogenen.” The French, e.g., Louis Glangeaud, called them the “Orogènes Biliminères.” This was in contrast to the “monoliminarity” of most of the Circum-Pacific tectonism.

From the lakes point of view, there were two very significant events in Tethyan history, which accompanied the progressive left-lateral shifts along the “Tethyan Megashear” zone of Sam Carey, once the leader of Tasmanian geology. First, there was the development

of a string of large interconnected lakes marginal to or in the depressions between the two converging orogenic belts, a zone known to the local geologists as the "Zwischengebirge" (the "betwixt" belt), seen today in the Pannonian Plain of Hungary, the submarine fracture complex of the Aegean, the Black Sea, and the interior plateaus of Anatolia and Iran. Also connected to them were "foredeep" basins in Bavaria, Romania and the Caspian Sea. The entire series was called the "Paratethys." During high eustatic phases the "lakes" became marine gulfs, but during low phases and orogenic compression that isolated the separate basins, gradual hypersalinity developed several times. The paleontologists noted the rapid evolutionary changes (particularly among the mollusca) with each rising salinity. The Black Sea has a history that also goes back into lacustrine phases (the "Euxine Lake"), ranging from fresh to hypersalinity. At times, as a result of freshwater intake, notably through the Volga drainage basin of Central Russia, the level of the Caspian Sea would rise so high that it overtopped the threshold of the Manych Depression, north of the Caucasus and flood into the Black Sea somewhat east of the Sea of Azov.

The other significant event in Tethyan history was the late Miocene closure of the Mediterranean, the so-called "Messinian Event" (6.5–5.3 Myr ago). Closures occurred in the Middle East (at the Aleppo Platform) and between Morocco and Spain (the Betic–Rif loop). Eventually there was a midpoint closure between Tunisia and Sicily. Thick deposits of salt and gypsum mark the evaporating pools of former lakes.

Thus, the present-day lakes of Europe are seen as largely the inheritance of geologic events that began 450–300 Myr ago and reached a crescendo during the last 5 Myr. Over this structural background is followed by a crowning veneer of processes related to the Quaternary glaciations. The finest lakes along the peripheries of the Alps are derived from the mountain and valley glaciers with their distinctive U-shaped valleys, the erosion of which was greatly enhanced by the contrasting uplifts of the Central Alps, and downwarping of their margins, e.g., in the south, Lakes Maggiore, Como, and Garda; in the west and north Geneva (Léman), Neuchatel, Zürich, Constance (Bodensee), and Chiemsee. Two of them are part of major drainage systems (Geneva in the Rhone; Constance in the Rhine). In the Dinaric Belt some major structural features included Lakes Ohrid, Prespa and Scutari.

The Scandinavian ice sheet, though far more extensive, did not inherit such dramatic contrasts, but nevertheless, in many areas, left vast numbers of small and even nameless lakes and depressions down to the level of kettle holes. Its major lakes (Vänern and Vättern) are primarily structural.

Postglacial isostatic recovery from the ice load is particularly noticeable in Scotland and Scandinavia. In places, old peneplains (or etchplains) on Precambrian platforms, e.g., Karelia in eastern Finland and Northwest Russia, are speckled with little depressions and their small

lakes. The broad surfaces of the Russian craton undulate into epeirogenic arches and depressions, the so-called "anteclise" and "syncline" structures, the latter being often the site of multitudes of isolated drainage systems, lakes, and swamps.

Meteorologically, most of Europe is within the trajectories of the prevailing westerlies which bring more or less perennial rains in many latitudes, with the seasonal swing to the north in Scandinavia and to the south in the Mediterranean belt. Oceanicity and continentality play important roles, the latter with increasing importance in eastern Europe, which is particularly characterized by its cold, dry winters. The monsoons of Asia and Central America do not reach Europe, but meridional turbulence often brings scattered summer rains in Southern Europe.

A few lakes in the European–Icelandic framework are directly related to volcanism, either contemporary or recently active in historical or Holocene times. Most famous of course is Vesuvius, near Naples, which erupted in A.D. 79, 1631, and 1944. Mt Etna, in Sicily, is active much of the time, recently in 2002. Stromboli, in the Tyrrhenian Sea was also erupting in 2002. On Iceland many historical eruptions have been recorded during the last 1,000 year, most recently Hecla (2000), Grimsvötn (1998) and Krafla (1984). In the eastern Mediterranean, the most spectacular eruption (and tsunami) was that of Santorini (Thera) in 1628 B.C. which destroyed the mythic city of Atlantis. Its most recent activity was in 1950. Traces of all these early eruptions are found in the bore cores of down-wind lake deposits.

These eruptions are not related in any way to the Circum-Pacific "ring of fire," but those in the Mediterranean belt are linked to motions of the "Tethyan megashear," and those in Iceland are connected with the seafloor spreading axis which bisects the island.

Some interesting crater lakes are found in a series of now-extinct centers, extending to north of Rome (Lago de Bolseno, L. de Trasimeno). The region of the "Puy" (in the Auvergne, southwest of France) is historically of great importance, because here, the geomorphic form of classical volcanic cones, lava streams, and so on was first recognized (1750–1775) by geologists (Guettard, Desmarest) although the activity is now quite extinct. That was in the early nineteenth century and it was several decades before their volcanic origin was universally conceded (Gohau, 1991).

Another area of well-preserved crater lakes ("maars") and clear signs of former volcanic activity is the Eifel district of western Germany. One of the most important eruptions dated by K/Ar methods at the Laacher See (3.3 km²), ash from which is traced in the lake deposits through Germany to Scandinavia. Maars (i.e., steep-sided, round basins, produced by pyroclastic gas eruptions) are also a feature of many Icelandic areas, with small lakes in the craters.

Also, eruptions of widespread significance are those associated with fault activity from Lake Balaton to the Tokaj area of northern Hungary, where the volcanic soils

have been a major factor in the cultivation of some magnificent wine grapes. Lake Balaton itself is the compound product of a complex fracture zone and the blocking of drainage systems by the volcanoes themselves.

Extraterrestrial impacts have created lake-forming depressions in two places in Europe, (a) the Ries crater, 29 km across, in the Swabian Alb of southern Germany and (b) a smaller site in central Sweden.

Coastal lakes in Europe fall into several categories, relating to their tectonic and eustatic histories: (a) Lagoons, with moderately saline to brackish waters, barred by sandy spits, and partly following the course of former river valleys, e.g., “*etangs*” in Southwest France, Northwest Mediterranean (Gulf of Lions), east coast of Corsica, and limans on the Northwest Black Sea. Openings to the sea in the French “*etangs*” are known as “*graus*.” Gravel spits occur in the south of England, e.g., Chesil Bank. (b) Lagoons with sandy barriers but with major fluvial input and permanent inlets from the ocean, e.g., Venice Lagoon, Italy; and at the major river mouths of eastern Spain. (c) Lagoons on major deltas, more or less frequently flooded by fluctuations of the main stream, e.g., the Danube, Rhone, Po. (d) Lagoons in the periphery of former glacial centers, as in the southern Baltic (where the lagoons are called *Haffe*, and the spits are *Nehrungen*, in German). In the UK, examples are the “*Norfolk Broads*.” (e) Lakes inherited from the tunnel valleys and meltwater channels of the last glaciation, e.g., the Limfjorden of northern Denmark. (f) Glacioisostatically uplifted lagoons or arms of the sea (“*loughs*”) in former glacial valleys, e.g., in Northeast Ireland: Lough Neagh; Strangford Lough, Belfast Lough, and Carlingford Lough are all open to the sea; in Scotland, Loch Lomond is 900 m deep, and was the site of the last glacial advance at the end of the Pleistocene.

Reservoirs and man-made lakes in Europe are quite innumerable and go back in time to the “*dew ponds*” of the Bronze Age. Giant barrages and associated lakes are generally absent except for several in Spain and Portugal, and a single major modification at Lake Mjøsa in Norway; also there are major engineering works in the former Soviet regions (Russia, Ukraine, etc.). They include Kuibishevskoe, Rybinskoe, Volgogradskoe, Kremenchugshoe, Tsimlyanskoe, Khakhovskoe, Gorkovskoe, Kamskoe, and many more.

Europe: lake categories

Epeirogenic basins, plateaus, and plains
(syncline, etc.)

The position of the lakes below are shown in (Figure 1), unless otherwise is stated.

1. *Lake Ladoga*, with 17,700 km² (6,835 square miles) is the largest lake in Europe. It is located northeast of St. Petersburg in Karelia (northwest Russia). It is fed by about 70 rivers, most important being the Svir River from Lake Onega (see below) and the Vuoksi River from Lake Saimaa. Its entire drainage basin is 258,000 km². Its outlet is through the Neva River into

the Gulf of Finland. It is linked by an extensive canal system with the Gulf of Finland, the White Sea and the Volga basin. Heavy rains in June and September cause the lake level to rise notably at those seasons. It is frozen in winter. Geologically its basin is tilted to the east and south, so that these shores are low and sandy, while northwestern shores are high and rocky, reflecting the glacioisostatic recovery of Fennoscandia.

2. *Lake Onega* (Onezhskoye Ozero), the second largest lake in Europe, is 9,630 km² (3,720 square miles), being located 130 km northeast of Lake Ladoga, which is fed by its overflow through the Svir River. Its surface elevation averages 33 m (108 ft), fed by a number of small streams. Its northwest shore is deeply indented by postglacial drainage channels. For a short period at the end of the Pleistocene, there was a continuous seaway from the White Sea to the Baltic. Maximum depth today is 138 m. It was connected by canals in 1852, and seagoing ships from the Russian Arctic can reach the Gulf of Finland, and through this “*Mariinsk Canal*” system, also the Caspian and Black Seas, except during the winter freeze-up (November to May).
3. *Lake Peipsi* (Chudskoye Ozero in Russian), forming part of the border between Estonia and northwest Russia. An extension in the south is Lake Pskov (710 km²). The combined area is 3,550 km² (1,370 cubic miles). The entire area to the east is low and swampy, but dry and undulating to the west. Its outlet is the Narva, flowing into the Gulf of Finland. Fed from the west by the Ema and from the south by the Velikaya. The whole drainage basin is 44,200 km².
4. *Ozero Ilman*, a shallow lake in Novgorod Oblast, 160 km south-southeast of St. Petersburg.

It varies in size with the seasons from 1,100 to 2,200 km² (425–850 square miles). It is fed by the Lovat and Msta rivers, and its outlet is the Volkhov which drains into Lake Ladoga. The entire area is low and swampy, extending over 66,300 km².

5. *Finland Lake District* occupies the eastern part of Finland (Keski-Suomi, Kupio, Pohjois-Karjala and Mikkeli), lying N of Helsinki, where a large number of interconnected water bodies trending roughly the northwest–southeast area relic of the last glacial stage of the Pleistocene. The general elevation is less than 100 m. Farther north, in Finnish Lapland, there are additional lakes and swampy areas that connect to the Barents Sea (Varangerfjord).
6. *Bug–Pripiet Marshes*, situated in eastern Poland, southern Belarus and western Ukraine, is a very extensive area of lakes and interconnecting rivers that eventually drain into the Vistula and the Baltic. The Polish sector is reserved as national parks (Poleski, etc.). (The Bug is sometimes called the “*Western Bug*” to distinguish it from the “*Southern Bug*,” or ancient Hypanis, that drains into the Dnieper and Black Sea.) A canal joins the Bug and the Pripiet and thence to the Dnieper. It rises in the Volyno-Podolsk uplands

Europe, Lakes Review, Figure 1 Position of European lakes described in the text.

(steppes), east of Lvov, an area of Precambrian basement rocks. The rivers are generally frozen from December to March.

7. *Masurian Lakes* (Jezioro Sniardwy, etc.), a string of small lakes in northeast Poland to the borders of Lithuania and to south of the Kalingrad Oblast (Russia; former East Prussia). The central area is designated as the Mazurski National Park. Very picturesque, the lakes, being a product of ice-age tunnel valleys, are mostly long and narrow. The largest is Sniardwy (122 km²) and the next is Mamry (104 km²). The surrounding forests are primeval and well preserved, together with their varied wildlife.
8. *Sea of Azov* (Azovskoye More) a generally shallow body of water (67,760 km², 14,517 square miles), situated in southern Russia between the southern Ukraine and the mouth of the Don River (Gulf of Tagenrog). It is connected to the Black Sea by the Kerch Strait.

It had been commercially exploited by the ancient Greeks (it was called "*Palus Maeotis*") who had established several small colonies there. Its sandy shores were very favorable for shallow-draft boats. There is a prominent sandspit, the "Tongue of Arabat" (*Arabatskaye Strelka* in Russian), some 230 km long, that projects from the west side. On the southeastern margin, there are a number of coastal lagoons. Its depth is everywhere less than 100 m and during ice-age desiccation it dried out several times.

Structural depressions (Graben, etc.)

1. *Lake Vänern*, the largest lake in Sweden, a product of block faulting in the Precambrian basement rocks, but modified by Pleistocene glacial action. It is 5,550 km² (2,100 square miles), draining southwest into the Göte River, which flows to Göteborg and the North Sea. Many rivers drain into it, notably the Klar which rises in Norway. Its drainage basin is

- 46,800 km². Canals connect Göteborg to Stockholm via Lakes Vänern and Vättern.
2. *Lake Vättern*, second largest of Sweden's lakes, with 1,900 km² (730 square miles). Its drainage basin is only 6,360 km² and thus much less than for Lake Vänern. Its structural form is a graben in the Precambrian basement, but its eastern margin is marked in part by early Paleozoic limestones. Glacial excavation further deepened the depression to 61 m below sea level.
 3. *Lake Mälaren*, a third structural depression in central Sweden, 1,140 km² (440 square miles), distinctive because it was formerly an arm of the sea. Because of glacioisostatic uplift (here, about 5 mm/year) the Earth's crust has risen so that it is now cut off (since A.D. 1200) at the city of Stockholm. About 1,000 year ago, Vikings from settlements along the lake could undertake trading (or looting) voyages to western Europe or using the rivers of eastern Europe could reach the Black Sea and eventually Baghdad.
 4. *Loch Morar*, the deepest glacial lake in Scotland (308 m, 1,017 ft), on the western coast, west of Inverness. Other glacial lakes are numerous, and oriented more or less radially because of the centralized Scottish ice cap, but most are modified by the structural foundations, the most extreme example being Loch Ness.
 5. *Loch Ness*, in Scotland, is almost unique in that it marks a major strike-slip fault zone (trending northeast–southwest) in a sinistral, left lateral sense. Its form was slightly modified by glacial erosion. It is 37 km (23 miles) long but only 1–2 km wide. It is 227 m (751 ft) deep, 57 km² (22 square miles). It is only the second deepest in Scotland, after Loch Morar (308 m, 1,017 ft).
 6. *Lake Mjøsa*, the largest lake in Norway, a glacially modified structural depression that is linked with other fracture zones to the Rhine Graben and others to the Rhone valley. Located in southeast Norway, in Oppland and Hedmark counties, north of Oslo, it covers 368 km² (142 square miles), and 99 km (62 miles) long. Other glacial lakes in Norway are more or less radially directed reflecting the maximum ice thickness over western Scandinavia, but modified by the structural foundations of the post-Caledonian fractures.
- Intermontane and intramontane basins**
- In the Tethyan orogenic belt, between the N-thrusted and the S-thrusted folded zones, there is a zone of intermontane basins, e.g., within the Pannonian basin, and in the inner parts of the twin orogenic belts which are strictly intramontane.
1. *Black Sea (Chernoya More: Russ.; Pontus Euxinus: Latin)*. It covers about 446,000 km² (180,000 square miles). This is the largest and most complex of the “Para-tethys” basins, and also the deepest. It has been in existence since the Miocene, and its salinity has fluctuated from nearly fresh to hypersaline, reflecting the patterns of the changing climates and the amplitudes of the intake discharges. The present waters are saturated with H₂S and lethal to most forms of life below a depth of about 90 m. Bordered to the north by the Crimea and western Caucasus, and to the south by the Pontic Ranges of Anatolia, it has only one outlet, the Bosphorus (to the Sea of Marmara and the Mediterranean). It is fed by many rivers, notably the Danube, Dniester, Bug (Southern), Dnieper, and Kuban (from Europe), and the Kizil Irmak and Sakarya (from Anatolia). At the Kerch Strait it is linked to the Sea of Azov and the river Don. From time to time, the Caspian Sea has overflowed into it via the Manych Depression north of the Caucasus, and generally out of phase with the periodic shrinking of the Black Sea, when a “Euxine Lake” is created.
 2. *Balaton* (Plattensee, in German), with about 600 km² (232 square miles), it is the largest lake in central Europe and occupies a fracture zone in the northeast–southwest structural trends of the Pannonian Basin of Hungary. Important volcanic cones (extinct) mark its northern shores. Its southern shore is low and sandy. Its maximum depth is 115 m. Its major feeder is the Zala River, and its outlet at Siofok to the Sio River eventually reaches the Danube.
 3. *Neusiedlersee* (Hungarian: Fertő-tó), is a shallow lake on the northwest borders of Hungary and southeast Austria, covering 318 km² (123 square miles). Its area is a National Park.
 4. *Lake Scutari* (Ligen-i-Shkodres in Albanian; ancient: *Palus Labeatis*) is located on the border between Montenegro (Serbia) and Albania, in a geological depression (graben) that is separated from but parallel the Adriatic. It covers 370 km² (143 square miles). It is fed from the north by the Morača River, and drains to the south into the Bunë and the Mediterranean.
 5. *Lake Ohrid (Lichnides of classical times)* is located partly in Albania and partly in Macedonia. It is the remnant of a large number of Miocene and Pliocene lakes that developed during late Neogene uplift in the Dinaride belt but were gradually filled in or bypassed. Lake Ohrid (32 km², 20 square miles) is 40 km long, picturesquely surrounded by steep mountains, and notable for retaining some of its original distinctive Neogene faunas. It is comparable to Lakes Prespa, Arissa and some smaller ones. Lake Ohrid is drained by the Crni Drim and its several lakes, eventually reaching the Mediterranean.
 6. *Lake Prespa* is situated 10 km southeast of Lake Ohrid to which it is linked by an underground karst channel, but has no surface outlet. It has a small appendage to the south, which makes a total length of 37 km (23 miles). The international borders of Albania, Macedonia, and Greece meet here.

Glacial troughs

1. *Lake Maggiore* (ancient: *Verbanus Lacus*) in northern Italy and southern Switzerland, a classical glaciated valley from the southern (Lepontine) Alps, is 210 km² (81 square miles), only 3 km (2 miles) wide but 64 km (40 miles) long. It is 370 m (1,220 ft) deep and is traversed by the Ticino River. Within it, there are four picturesque islets (the Borromean Is.).
2. *Lake Como* (ancient: *Comum Lake*) situated east of Lake Maggiore in the Lombardy province of North Italy. It is traversed by the Adde River. The lake is 130 km² (50 square miles), 60 km long and only 5 km across. Slightly to the west is a smaller body the *Lake of Lugano* (*Lacus Ceresius*, in Latin) about 49 km² (19 square miles), and 286 m (945 ft) deep.
3. *Lake Garda* (ancient: *Lacus Benacus*) is located in eastern Lombardy in North Italy, bordering Veneto. It is 52 km (30 miles) long, and up to 17 km across, spanning 370 km² (143 square miles). It drains to the south into the Mincio River and eventually the Po and the Adriatic.
4. *Lake of Geneva* (*Léman* in French; ancient: *Lake Lemanus*), situated partly in Switzerland, partly in France. It covers 580 km² (224 square miles), 75 km long and up to 15 km across. From east to west it is traversed by the River Rhone which rises in the Bernese Alps and discharges into the Mediterranean. It was here that the first optical effects of warming air over cooler lake water (mirage) were observed and recorded. Also observed here were the submarine landslides caused by Rhone flooding at the eastern end. The lake is also notable for its seiche response to sudden wind reversals.
5. *Lake of Neuchatel* is situated in northwest Switzerland on the edge of the Jura mountain belt. It is 135 km² (84 square miles) in area, and 150 m (502 ft) deep. Closely linked to it east-northeast is a smaller body, the Bielersee in the Canton Bern, which is drained by the Aare River, a tributary of the Rhone.
6. *Lake of Zürich*, the largest of a cluster of glacial lakes in east-central Switzerland, 88 km² (34 square miles), 40 km (25 miles) long and narrow, 1,538 m (469 ft) deep. Others in this group include the Wallensee (24 km², 9 square miles) and Zügersee (39 km², 15 square miles). Wallensee is linked by the Linth Canal to the Lake of Zürich.
7. *Lake of Lucerne* (*Vierwaldstättersee* in German) (in between Lake Neuchatel and Lake Zurich - not shown in Figure 1) has a star shape with branches into four cantons: Schwyz, Uri, Unterwalden and Lucerne. It covers 114 km² (44 square miles), is 38 km (24 miles) long, but only 10 km wide. Its main input is from the river Reuss, entering in the south at Flüellen, and leaves at the city of Lucerne. It is famous in the history of geology as the place where strong overfolds and faults were first recognized in the exceptionally clear and continuous outcrops along the sides of the lake. Also in human history (twelfth century) for the site of the alleged marksmanship of William Tell (at Altdorf).
8. *Lake Constance* (*Bodensee* in German; *Brigantinus Lacus* in Latin), located on the eastern border of Switzerland with Germany and (in a short sector) with Austria, it is traversed by the river Rhine, which enters in the southeast and leaves through another small lake, the Zellersee, in the west-northwest. It is 554 km² (210 square miles), 74 km (46 miles) long, up to 13 km (8 miles) across, and has a maximum depth of 250 m (827 ft). The waters have a seiche response to sharp change of wind direction. Stone-Age people had lake dwellings (about 2700 B.C.) along the shore when the lake level was lower than today.
9. *Ammersee* (west of Chiemsee - not shown in Figure 1) is one of a series of moraine-dammed lakes that mark the Bavarian foothills of the Eastern Alps. It is 48 km² in area, and located 34 km (21 miles) west-northwest of Munich. Dated moraines match each of the major glacial advances in the Alps.
10. *Chiemsee*, the largest lake in Bavaria and one of the series that occupy the foothills of the Eastern Alps. It is 64 km (40 miles) east-southeast of Munich. It is 80 km² (31 square miles) at 514 m (1,699 ft) above sea level. Its outlet through the Alz joins to the Inn, and eventually the Danube.
11. *Attersee* - not shown in Figure 1 (or *Kammersee*), in upper Austria, 55 km east of Salzburg. It continues the series of glacially formed lakes that span southern Bavaria. It is 45 km² (17 square miles) in area.
12. *Traunsee* (*Gmundnersee*), in upper Austria, one of a series that mark the Salzkammergut of the Eastern Alps, 25 km² (9 square miles) in area. They are notable for their picturesque settings.
13. *Hallstättersee* (not shown in Figure 1) is one of the Salzkammergut lakes, only 8 km² (3 miles), but famous for its early Iron-Age culture (dated about 900 B.C.), with its multiple graves and art objects, discovered in 1846–1899.
14. *English Glacial Lakes*, notably *Lake Windermere*, 32 km (10 miles) long and the largest in England. Windermere is the site of paleomagnetic measurements going back over 10,000 year. The “Lake District” is a star-shaped cluster of 17 major lakes, designated as a national park, and made famous particularly by the poet William Wordsworth (1770–1850), who lived at Grassmere. Many of the lakes are known as “meres” or “waters” while the small, up-valley ones are “tarns.”
15. *Scottish Glacial Lakes*, notably *Loch Lomond*, 70 km² (27 square miles), the largest lake in Scotland, typically long and narrow (38 km, 24 miles long), and reaching 180 m below sea level. Most of the other glacial lakes of Scotland are dominated by structural

foundations (see under section Structural depressions [Graben, etc.]). The “Loch Lomond Readvance” was a brief but distinctive reversal of the last general deglaciation, at the time of the “Younger Dryas” (dated about 10,500 year BP).

16. *Glen Roy* (not shown in Figure 1), site of a former glacial lake, situated to the southeast of Loch Ness, that was once blocked by the ice. As the glacier receded in steps, each was marked by an erosion bench, probably amplified by abrasion caused by ice on the lake, resulting in a series as a succession of “Parallel Roads.” For many years, the “Parallel Roads of Glen Roy” were an enigma until the glacial theory became thoroughly developed.
17. *Icelandic glacial Lakes*. With its geotectonic situation on top of the mid-Atlantic seafloor spreading zone, Iceland can be expected to display a wide variety of lakes, and because of its mean latitude, 65°N latitude, most of them are related to glaciation. One exception is Öskjuvatn in the Nordurland Eystra division, a crater lake, close to the northeast–southwest spreading zone. Most of the overdeepened glacial troughs are occupied by long, narrow lakes, e.g., Lagerfljót (Austurland). Many are irregular, moraine-dammed, e.g., Myvatn (Nordurland Eystra), Pingvallavatn (Sudurland), and Blöndulón (Nordurland Vestra). Around the coast, there are many blocked estuaries in old glacial troughs, as well as barred embayments, e.g., Leirur and Hornafjörður. There are also some broad areas in the interior marked by numerous thermokarst lakes and swamps, e.g., Arnarvatnsheidi.

Glacio-isostatic lakes

1. *Torneträsk*, in the Swedish far north (Lapland), which is long and narrow, oriented west-northwest–east-southeast. It is cut off by the isostatic uplift from the inner limit of the Narvik Fjord of Norway. The area is a National Park, with a scientific research station at Abisko. The railway from the iron mines at Kiruna to Narvik follows the southern border of the lake. The lake’s outlet is now to the east and forms the eastern border of Sweden with Finland before discharging into the Gulf of Bothnia, and thus the Baltic.
2. *Akkajaure*, situated farther south, also near the Norway–Sweden boundary, this lake eventually drains into the Luleälven to debouch into the Gulf of Bothnia at Lulea. It is likewise a National Park area. Numerous other reversal drainage systems mark the border areas to the south, e.g., the Angermanälven and Indalsälven (that debouches near Sundsvall). These valleys were former lakes that became important in the Quaternary world history because of their varved clays in the old lake deposits that enabled Baron E. De Geer (in 1910) to calculate the absolute ages of the Holocene. Recently, the deposits were systematically resampled and the original timetable (with small revisions) was confirmed.

3. *Enarejärvi*, an important isostatic lake about 75 km long in Finnish Lapland, situated about 150 km southwest of Kirkenes on the Varanger Fjord, an inlet from the Barents Sea (part of the Arctic Ocean). The isostatic uplift along the coast and climatic fluctuations here can be measured by the cyclical steps of the uplifted beachridges. The emergence began about 12,000–13,000 year ago. The lake has no outlet but is surrounded by peat swamps that extend about 500 km southward to central Finland (see Oulujärvi).
4. *Pya-Ozero*, another isostatic lake, located about 80 km southwest of Murmansk in the northwestern corner of Russia. It is connected by the Tuloma River to the Kola River near Murmansk. The Kola River drains a number of similar lakes near Apatity. To the east of here is the Kola Peninsula which is rimmed by uplift terraces but on a reduced scale compared with those of the Varanger Fjord.
5. *Oulujärvi*, Finland’s fourth largest lake, is about 50 km across, 1,041 km² (387 square miles), 160 m above sea level, and located about 75 km southeast of Oulu on the Gulf of Bothnia. It is drained there by the Oulujoki River. From here northward for 800 km to the region of Inarijärvi, there is a continuous belt of peat swamps with scattered lakes (*jaure*, and *javvre* mean “lake” in Lappish) which are interconnected through Kemijärvi Lake and the Kemijoki River to the northern end of the Gulf of Bothnia. The entire gulf area is still rising (at several mm/year) following the retreat of the Fennoscandian ice sheet. The retreating sea levels are marked by beach ridges separated by low, swampy areas.
6. *Lake Päijänne* (not shown in Figure 1) is in south-central Finland covering 1,506 km² (560 square miles), and 75 m above sea level. Although its bedrock is Precambrian granite-gneiss, there is superficial morainic material which affords material for some sandy beaches. In the summer season, when the lake is not frozen, it is linked by with nearby lakes by an extensive canal network for the logging industry.

Karst lakes, and others of lithic controls (these lakes are not shown in Figure 1)

Karst lakes are, by definition, restricted to limestone terrain and are generally very small and associated with cryptorheic drainage systems. In the European area, they are mostly found in the Mesozoic deposits of the old Tethyan seaway, notably in the Dinaric belt of Croatia, Slovenia, Bosnia, Albania, and Greece.

1. *Plitvice Lakes*, located in Croatia, 100 km (65 miles) south-southwest of Zagreb. There are 16 of these lakes that drain eventually into the Kupa River that joins the Sava below Zagreb. The area is preserved as a national treasure. The world’s classical karst areas (“kras” is the word in Croatian) are located in this region.
2. *Brenne and Sologne Lakes*, on the northern margin of the French Massif Central, are not karstic but are

related to the detrital granitic sands transported to the north, and produce a “hydromorphological” unit that is studded with small lakes, a national park.

Volcanic lakes (these lakes are not shown in Figure 1)

Crater lakes (“Maaren” in German) are best known in the Eifel district of Germany and in the Auvergne of the French “Midi” (e.g., the “Puys,” in French). They are extremely small but are geologically most interesting.

1. *Laachersee*, in the Eifel 25 km northwest of Koblenz, which is the site of a major eruption in the early Holocene that spread identifiable ash over much of northwestern Europe. (The glass shards are uniquely correlated with this particular event.)
2. *Monts Doré*, in the French Auvergne, designated as the “Parc Naturel Régional des Volcans d’Auvergne,” this was an important area in the history of geology, because of the cones and their lavas as being first recognized as volcanic, although totally extinct.

Coastal lagoons (these lakes are not shown in Figure 1)

1. *Etangs* of southwest France. Barred by littoral dunes in the Landes area, these include Etang de Biscarosse to E. de Carcans, situated respectively southwest and northwest of Bordeaux. Farther north is one at Les Sables d’Olonne in the Vendée and the Marais Breton, south of the River Loire.
2. *Etangs* of the Golfe du Lion of southern France (Languedoc-Roussillon). These include the Etang de Canet, Leucate, Lapalme, and Ayralla. Radiocarbon dates show their progressive evolution with successive Holocene beachridges building out seaward.
3. *Albufera*, on the Spanish Mediterranean coast just south of Valencia, which was a broad embayment cut off by a major baymouth bar. A similar example south of Alicante is the *Laguna Salada* and an incompletely enclosed embayment, Mar Menor Los Alcázares.
4. *Doñana*, marking the mouth of the Guadalquivir River and a wide swampy area, the Marismas, is protected as a National Park.
5. *Algarve lagoons* of southern Portugal, a national park, with some openings in the barrier islands (Cabo de Santa Maria).
6. *Lagoa de Santo Andre* (and others) situated on the southwest coast of Portugal.
7. *Rio de Avoiro*, on the west coast of Portugal between Coimbra and Oporto, a many fingered embayment, cut off by a long barrier island.
8. *Etang d’Urbino*, on the east coast of Corsica and several smaller ones, Biguglic, Diana, and Palo. All are related to the extreme periglacial activity in the mountains and the fluvial transportation of frost debris to the coast, thus providing an abundant supply of sand for the baymouth bar building.
9. *Stagno dè Cabras*, also *Stagna di Santa Giusta*, with multiple baymouth bars, on the west coast of Sardinia, northwest of Cagliari.
10. *Laguna di Orbetello*, a classic site of a triple tombolo on the northwest coast of Italy about 100 km northwest of Rome. Dating of the tombolo spits is aided by the presence of fish tanks from the classical (Roman) period.
11. *Lago de Massacinerò*, situated 15 km north of Pisa on the Italian west coast, the bayhead bars being fed by the abundant sediment brought down by the Arno.
12. *Laguna Veneta*, situated at the head of the Adriatic, north of the Po delta, and that of the Adige. The city of Venice is located on an island in the lagoon, which has several natural openings. A smaller but rather similar lagoon (*Laguna di Marano*) is located about 45 km to the east. And another, *Valli di Comacchio*, is situated to the south, about 15 km north of Ravenna.
13. *Lago di Lesino* and *Lago di Varano* are situated side by side on the N border of the Gargano Peninsula. Both are contained by regular baymouth bars.
14. *Lago di Fogliano*, *Caprolace* and *Sabandia* are located in a line NW of Monte Circeo, 90 km south-east of Rome, and site of a famous Neanderthal cave. The pre-Last Glacial sea level has left a distinctive notch in the cave.
15. *Limnithalassa Mesolongiu*, is situated on the Gulf of Patras in western Greece, just east of the Achelooos delta. This river drains a number of structural-depression lakes in the interior. The *Limnithalassa* includes a large number of islets but also wide openings to the sea (Ionian Sea).
16. *Limans of Danube Delta* (*Lacul Razim* etc.), the south side being in Romania and the northern side in Ukraine (Odessa Oblast), where the classical limans were first described on the lower Dniester, the southern Bug and other rivers. The limans are a series of lagoons separated by barrier islands in succession, apparently repeated due to climatic fluctuations and associated submergence.
17. *Zuider Zee*. Prior to the thirteenth century there were a series of lakes and swamps in the IJssel valley of east-central part of the Netherlands, but in the early Middle Ages the barrier to the Waddenzee (and North Sea) was breached by storms and eustatic rise. The *Zuider Zee* (“South sea”) then became a reality, as an oceanic inlet. In the twentieth century a new North Sea dike re-created the Isselmeer, but only briefly, as segments became cut off by polders.
18. *Norfolk Broads*. Part of eastern Norfolk became drowned by eustatic rise during the middle Holocene, but crustal movement has subsequently provided uplift and isolation of much of the area into a succession of lagoons, which are nevertheless partly tidal.

19. *Jadebusen* and other embayments in northern Germany (Friesland), have undergone somewhat similar histories of evolution from lagoons or lakes to marine gulfs.
20. *Ringkøbing Fjord* on the west coast of Denmark is a regular barred embayment about 30 km long. (In spite of its name, it is totally unrelated to the normal geological landform "Fjord.") Its barrier is known as the "Holmsland Klit." Numerous small lagoons occur farther north, including "Nisum Fjord."
21. *Limfjorden*. The "Nisum Bredning" provides access to the giant "Limfjorden" that separates the whole of northern Denmark from the North Sea (Skagerrak). The origin of the Limfjorden appears to be the isostatic uplift from deglaciation associated with crustal tilting to the south, that is superimposed by the oscillatory ripple effect created by the Holocene eustatic fluctuations. (The Limfjorden phenomenon appears to be almost replicated in Northeast Germany by the Boddensee complex, see below.)
22. *Boddensee, Hiddensee, Jasmunder Bodden*, and related embayments near Rügen in Northeast Germany, facing the Baltic Sea, have undergone alternate lacustrine and marine inundation histories during the Holocene. All are linked to the Baltic by inland channels, and only the "Kleine Jasmund" is isolated. Today, these are national park systems, the Boddenlandschaft and Rügen-Jasmund, which are followed to the southeast by the Greifswalder Bodden (open to the sea and linked to the others by the Stralsund channel) and the Insel Usedom (which is not). The interplay here between Holocene fluctuating eustasy and the ripple effect of the postglacial isostatic movements attracted particular attention from the Shorelines Commission of the International Union of Quaternary Studies in the period 1960–1970.
23. *Oderhaff Haffküste/Zalew Szczeci/Eski* is an extensive lagoon near the mouth of the Oder/Odra River which here forms the boundary between Germany and Poland (and hence the multiple names). Postglacial isostatic uplift and strong longshore sediment transport combine to build a massive barrier at the mouth of this major river. Smaller lagoons are created farther east (Jamno, Bukowo, Kopan). Some 50–100 km south of the coast, there is a broad arc of uplift that from the region of Lübeck in the west to Gdansk in the east, that has blocked river valleys to create numerous tectonic-barrier lakes, known as the "Pomeranian Lake Belt" (Podjezierze Pomorskie).
24. *Wisłany (Vistula) Lagoon*, in the east part of the Gulf of Gdansk is a classic barred embayment, the early German works on the subject refer to this type of bar as a "Nehrung" ("Mierzeje" in Polish). In the western part of the Gulf a new spit, the "Promontory of Hel," named for the settlement "Hel" at its SE tip. The bar has been nourished by sediments carried down by Poland's largest river, the Vistula (*Wisła* in Polish, *Weichsel* in German). To confuse matters, the eastern part of the Wisłany Lagoon, formerly part of East Prussia, is now a segment of the Russian Federation, and has a Russian name, the Kaliningradskiy Zalif.
25. *Courland Lagoon* (Kurische Haff, in German) lies partly in the Kaliningrad province (Russia) and partly in the southwest corner of Lithuania, where it is protected as a national park. Its baymouth bar ("Nehrung") is 100 km long, from Zelenogradsk in the south to Klaipeda in the north. Farther north on the Baltic coast, there are some smaller lagoons, in Latvia and the Gulf of Riga.

Reservoirs and man-made lakes

Europe is probably the oldest reservoir-building society, going back to the times of Greek and Roman urbanization. Rainfall collection on a house-by-house basis probably extends several millennia earlier, but a plentiful supply of water only became a social necessity when houses were built close together and required some sort of hygienic waste disposal. Deep conduits have been found by archeologists working on the foundations of Jerusalem, and water was needed for flushing them. Multi-seat marble toilet services were provided in the Greco-Roman colonies of North Africa and are still freshly preserved because of burial for many centuries under Saharan sands.

Reservoir and canal construction for irrigation purposes were probably initiated in Babylon (modern Iraq) and other communities along the two great rivers, the Tigris and Euphrates, of Mesopotamia, as early as 5000 B.C. The seasons are very contrasted and the floodwaters of the two great rivers would demand some sort of human control. Direct evidence is lacking, but probably began with the simplest forms of earthen channels that leave no archaeological evidence. The same seasonality is also a feature of the Nile and in pharaonic times (probably even the First Kingdom) the social organization was in place for irrigation management.

In Europe, great rivers with their seasonal flooding exist in the case of the Danube, the Rhine, the Rhone, and a few others, but early social organization for the utilization of their waters appears to have been lacking. It was only with the development of centers of urbanization associated with the imperial organization of Rome, with road building and city planning, that systematic hydrologic services were seen as a necessity. It seems to be a sad fact that only the discipline of that Roman power could maintain these services. Many fall into disrepair. Others were simply neglected by the scattered tribes that followed the A.D. 400 breakdown. It is interesting that organized Christian religiosity was a curious factor in the moral rejection of communal bathing and the general disappearance of public bath houses.

With the intellectual renaissance that followed the reign of Queen Elizabeth I and her scientific advisors, a gradual

reassertion of the importance of hydrology began. It was only in the reign of Queen Victoria that the first operating water-closet was introduced, and thus the beginning of the end of the “great unwashed.”

EUTROPHICATION IN FRESH WATERS: AN INTERNATIONAL REVIEW

Malcolm Farley
 Malcolm Farley Associates, Alvescot, Oxfordshire, UK

Definition and Introduction

Aquatic eutrophication: from the Greek “eutrophia”, meaning “well nourish”.

Eutrophication is defined by the European Commission, in the Urban Waste Water Treatment Directive as:

The enrichment of water by nutrients, especially compounds of nitrogen and phosphorus, causing an accelerated growth of algae and higher forms of plant life to produce an undesirable disturbance to the balance of organisms and the quality of the water concerned.

In a foreword to its report on Water Quality: The Impact of Eutrophication, the United Nations Environment Programme (UNEP) notes that:

Eutrophication is one of the most widespread environmental problems of inland waters, and is their unnatural enrichment with two plant nutrients, phosphorus and nitrogen. Such changes can destroy wildlife habitats and interfere with a range of water uses from recreation to the production of drinking water.

Origin of the concept of eutrophication in fresh waters

The idea of eutrophication began with limnologists. Early in the twentieth century, northern European limnologists distinguished *oligotrophic* from *eutrophic* lakes. The former were nutrient-poor, the latter nutrient-rich.

Hutchinson (1973) reviewed the early development of ideas about eutrophication. In 1907, C.A. Weber invented the (German adjectival) terms *eutrophe*, *mesotrophe* and *oligotrophe* to describe different states of the flora in German peat bogs as the bogs changed with time through accumulating material. Hutchinson wrote:

At first the bog vegetation was what Weber called eutraphent, requiring high concentrations of essential elements in the soil

solution; at the end of the process (as the bog level built up above its surroundings, and became more leached) an *oligotraphent* flora covered the bog, composed of species tolerating very low nutrient concentrations.

Naumann (1919) used Weber's terms in a discussion of phytoplankton in Swedish lakes. He began by considering water types, which might be *oligotrophic*, *mesotrophic* or *eutrophic* depending on their content of mineral nutrients – as water might be labeled fresh, brackish, or marine depending on its salt content. However, chemical techniques available to Naumann did not allow nutrient concentrations to be reliably measured, and so he redefined the categories to apply to lakes, according to their appearance in summer and the most abundant types of phytoplankton. Other studies of European lakes supported the idea about distinctive floras, with the thick-walled green algae called desmids seen as the characteristic phytoplankters of the oligotrophic lakes of mountainous regions, and diatoms and blue-green bacteria seen as characteristic of eutrophic lowland lakes.

Stratification

Using data from North America and Germany, Thiennemann (1918) showed that some stratified lakes experienced severe oxygen depletion in the *hypolimnion* (the water beneath the seasonal *thermocline*). Adding these findings to Naumann's definitions gave the *oligotrophic–eutrophic paradigm* (Figure 1).

At certain times, lakes may form a *thermocline* some meters below the surface (Figure 2). In the thermocline, the temperature declines several degrees over a few meters and divides the lake into two zones an upper warmer one, the *epilimnion*, and a lower colder one, the *hypolimnion*. Lakes in temperate regions usually have depths of 5–10 m or more. Such lakes typically form a thermocline during the summer time and stratify. Shallow tropical lakes can also stratify, but stratification can be broken down by strong winds.

A thermocline prevents the upper and lower layers of the lake from mixing. The result is a change in vertical oxygen concentrations, where concentration is high in the upper layer or epilimnion and very low in the lower layer or hypolimnion. The low oxygen concentration may degrade water quality downstream of the lake or

Eutrophication in Fresh Waters: An International Review, Figure 1 Thiennemann's *oligotrophic–eutrophic paradigm*.

Eutrophication in Fresh Waters: An International Review,

reservoir, particularly downstream of reservoirs with short retention times.

Stratification and mixing were the subject of research by Lack and Lund based on observations in the small lake Blelham Tarn, in the English Lake District. They describe the dynamics of stratification in three stages:

- The surface-mixed layer or epilimnion
 Absorption of the sun's heat in near-surface waters creates stability because warm water is buoyant. Heat is lost from water to air directly and through evaporation of water – this cools the surface layer and also mixes it convectively. Mixing is also caused by wind. The surface mixed layer first forms in spring, when the stabilizing effects of heating exceed the mixing effects of stirring by wind and night-time cooling.
- The (seasonal) thermocline and internal mixing
 The seasonal thermocline is the upward retreat of the surface-mixed layer, at its most developed in late summer. Weak internal mixing in the thermocline results from internal waves which break in the thermocline and along the lake walls. This mixing is too weak to break down the thermocline during summer but may slowly transfer deep water nutrients into it. The hypolimnion is the bottom water of a lake, actually the lower part of the thermocline.
- Surface cooling and the autumn overturn
 During autumn the epilimnion loses heat and cools, and gradually deepens, entraining deeper water from the thermocline and then the hypolimnion, until eventually the entire water column is mixed.

Production

By the 1960s, limnologists had developed reliable and sensitive methods for measuring the concentrations of chlorophyll and nutrients in lakes and were beginning to collect time series showing changes during the year. The simplest analysis of these data involves plotting summer chlorophyll on winter-dissolved nutrient, either from one lake in many years, or from many lakes. The yield is the ratio of (summer) chlorophyll to initial (winter) nutrient, and the rationale is that phytoplankton is negligible in winter, when nutrients are abundant; the growth of phytoplankton during the spring converts all available nutrients into phytoplankton.

Some workers, however, plotted chlorophyll averaged over the year against "mean total nutrient". In the case of P, the latter includes all forms of the element in the water column. In winter it is mostly present as dissolved phosphate, but, by summer, most of it is contained in organisms, detritus, or dissolved organic P. In the case of N, the total includes particulate organic N, dissolved organic N, and the dissolved inorganic compounds nitrate, nitrite, and ammonium; but not dissolved nitrogen gas, which is not usable by most plants.

The total nutrient approach can be seen as giving improved prediction of initial nutrient on the basis of all-year data, if it is assumed that re-mineralization of organic forms of a nutrient will contribute to next winter's dissolved inorganic nutrient. It also allows for the uptake of dissolved organic nutrients by some phytoplankton. The comparison of winter nutrient with summer chlorophyll is conceptually simpler. In either case, the existence of a statistically significant correlation between chlorophyll and nutrient has generally been taken as implying nutrient limitation of biomass, with the slope of a regression line giving the yield ratio. In studies carried out in the "Experimental Lakes Area" of Ontario a group of lakes was set aside to observe the effects of adding nitrate and phosphate (Johnson and Vallentyne, 1971; Schindler et al., 1971, 1978).

Schindler (1977) concluded that

Evidence has mounted for an astonishingly precise relationship between the concentration of total phosphorus and the standing crop of phytoplankton in a wide variety of lakes, including many in which low nitrogen-to-phosphorus ratios should favor limitation by nitrogen.

Schindler also demonstrated that knowledge of total P also explains much of the variability of total N in the experimental lakes. He commented that

The nitrogen content of a lake increases when the phosphorus input is increased, even when little or no nitrogen is added with fertiliser.

Indicators of lake trophic status

The concentration and availability of plant nutrients in a water body is determined by its catchment, which in turn is influenced by the geology. Thus waters vary in their nutrient status.

The trophic status of lakes has been defined in terms of primary production – i.e., the amount of organic carbon made by photosynthesis under each square meter of the lake's surface during a year. The measurement of primary production requires specialized skills and equipment. Rodhe (1969) gave the following values ($\text{g C m}^{-2} \text{ year}^{-1}$):

- Oligotrophic 7–25
- Eutrophic (natural) 75–250
- Eutrophic (polluted) 350–700

Trophic status has also been defined, using more easily measured variables to categorize the trophic status of freshwater, by the Organisation for Economic

Co-operation and Development (OECD, 1982). The scheme uses information about:

- The concentration of Phosphorous (P), the limiting nutrient
- The concentration of Chlorophyll a (the green plant pigment needed in photosynthesis)
- Transparency

Transparency is measured with a *Secchi disk*. The disk is a 20 cm disk with alternating black and white quadrants. It is lowered into the water of a lake or reservoir until it can be no longer seen by the observer. This depth of disappearance, called the Secchi depth, is a measure of the *transparency* of the water. Transparency can be affected by the color of the water, algae, and suspended sediments.

The scheme has three main trophic classes:

- Oligotrophic for nutrient poor waters
- Mesotrophic for waters slightly to moderately enriched with nutrients
- Eutrophic for waters excessively enriched with nutrients

There are also two boundary classes:

- Ultra-oligotrophic for extreme nutrient deficiency
- Hypertrophic for extreme eutrophication

The trophic categories and their measurement criteria are listed in [Table 1](#).

Effects of eutrophication

Nutrient enrichment tends to stimulate phytoplankton, and one important result is increased growth of *algae* (microscopic floating plants), and *macrophytes* (larger plants). Microalgae and cyanobacteria usually grow faster than larger algae or plants. The resulting biomass absorbs light, shading out benthic microalgae or macrophytes. In flowing waters, however, phytoplankters tend to be washed downstream, and attached plants may be stimulated instead. In some freshwaters the result of enrichment is the stimulation of floating macrophytes such as duckweed (*Lemna*) or the water fern *Azolla*.

Some macrophytes form dense mats of larger floating plants such as water hyacinth, *Eichhornia* ([Figure 6](#)) and Nile cabbage. Growth results from the process of photosynthesis, which is how the plants generate organic compounds and biomass through the uptake of nutrients (nitrogen, phosphorus, and others) from the soil and water.

In the process, light acts as the energy source and carbon dioxide dissolved in water as the carbon source. As a result of the photosynthetic process oxygen is also produced.

When plants die, they decompose due to bacterial and fungal activity. In the process, oxygen is consumed, and the nutrients are released together with carbon dioxide and energy. In many lakes and reservoirs in the world, plants growing in the surface during spring and summer will die during autumn and sink to the bottom where they decompose.

During spring and summer, lakes and reservoirs are often supersaturated with oxygen due to the amount of plants. The oxygen surplus is released to the atmosphere and no longer available to decompose organic matter. This causes oxygen depletion or anoxia in the deeper layers of lakes, particularly in autumn. Oxygen depletion is therefore caused by the shifts in time and space between photosynthesis and decomposition. In tropical areas, the same process takes place, but seasonally speaking, it is not as representative as in temperate areas because temperature and daylight duration is very similar throughout the year.

Oxygen depletion often leads to complete deoxygenation or *anoxia* in the deep layers of the lake or reservoirs also because oxygen poorly dissolves in water. In shallow lakes and where plant production is high, deoxygenation of the sediment and water also occurs. Such conditions kill fish and invertebrates. In addition, ammonia and hydrogen sulfide formed by bacterial activity can be released from sediments under conditions of anoxia, and their concentrations can rise to levels which adversely affect plants and animals. Phosphorus and ammonia may also be released into the water, further enriching it with nutrients.

Some particular types of algae, which grow in highly nutrient enriched lakes and reservoirs – blue-green algae or cyanobacteria, and dinoflagellates which produce red tide – release in the water very powerful toxins which are poisonous at very low concentrations. Some of the toxins produce negative effects on the liver of livestock at minimal concentrations, but they can lead to the death of cattle and other animals even to humans when ingested in drinking water at higher concentrations.

High concentrations of nitrogen in the form of nitrate in water can also cause public health problems. They can inhibit the ability of infants to incorporate oxygen into

Eutrophication in Fresh Waters: An International Review, Table 1 OECD criteria for trophic status of lakes

Trophic category	Mean total P, $\mu\text{g L}^{-1}$	Mean $\mu\text{g Chl a L}^{-1}$	Max. $\mu\text{g Chl a L}^{-1}$	Mean Secchi depth, m	Min. Secchi depth, m
Ultra-oligotrophic	<4	<1.0	<2.5	>12	>6
Oligotrophic	<10	<2.5	<8	>6	>3

Hypertrophic	>100	>25	>75	<1.5	<0.7

their blood and so result in a condition called the blue baby syndrome or methemoglobinemia. For this to occur, nitrate levels must be above 10 mg per liter in drinking water. The condition can be life-threatening.

One of the main problems occurring as a result of algal blooms or other aquatic plants is the reduction in transparency in the water which reduces the recreational value of lakes, particularly for swimming and boating. Water hyacinth (Figure 6) and Nile cabbage can cover large areas near the shore and can float into open water spreading at times over the entire surface. These mats can block light to submerged plants and produce large quantities of dead organic matter that can lead to low oxygen concentrations and the emission of unpleasant gases such as methane and hydrogen sulfide due to its decomposition or decay. Masses of these plants can restrict access for fishing or recreational uses of lakes and reservoirs and can block irrigation and navigation channels.

Shifts in the abundance, and significant reduction in diversity of species (biodiversity), of aquatic organisms within a lake or reservoir may also be caused by eutrophication. This results from the changes in the water and food quality together with decreased oxygen concentration which often alter the composition of the fish fauna from more to less desirable species. Nevertheless, yields of certain species of fish tend to increase as eutrophication increases since there is more food available. However, oxygen depletion and high ammonia concentrations under hypertrophic conditions can lead to decreases in fish yields as eutrophication rises.

Nutrient enrichment

The growth of plants in aquatic systems is influenced by a number of factors including:

- The supply of nutrients
- Light
- Temperature
- Water flow
- Turbidity
- Zooplankton grazing
- Toxic substances

The properties of the catchment and the water body and the impact of human activities affect these factors. While it is important to understand the role of all these factors it is widely accepted that the principal factor ultimately controlling the growth of algae and plants in natural waters is the supply of *nutrients*.

In temperate freshwater systems, phosphorus is generally the key limiting nutrient. It may occur as soluble inorganic compounds such as phosphate (PO_4^{2-}) or hydrogen phosphate (HPO_4^-). It may also occur as soluble organic compounds such as proteins and lipids. Both the inorganic and organic compounds may also strongly absorb to or react with mineral surfaces, including clays and colloidal materials, and therefore be transported with fine particulates in the water. Chemical and microbial processes in the soil,

water, and sediments can transform the phosphorus from one compound to another, and affect its availability as a nutrient. Hence concentrations of phosphorus are normally reported as the element P rather than say the concentration of the phosphate ion (PO_4^{2-}). However, phosphate, either dissolved or bound to particulate matter, is normally the phosphorus compound directly responsible for the majority of eutrophication events in freshwaters.

There are exceptions. In some freshwaters silicon may limit blooms of diatoms in spring. In areas where phosphate levels are naturally high because of the underlying geology, water bodies may be limited by nitrate (NO_3^-), as in the meres of Shropshire and Cheshire in the UK. Estuaries may be limited by phosphorous at their freshwater extreme, grading through to nitrogen-limitation at their seaward end. But the common occurrence of suspended sediments and consequential turbidity in estuaries often means that light limits algal growth. Where nutrients are the limiting factor in coastal waters nitrogen as nitrate is generally believed to be the key nutrient. This is supported by recent Australian research.

Australian science has made rapid advances in the last decade in understanding eutrophication processes in inland waters and estuaries. The freshwater research on which these advances are based was triggered by well-publicized blooms of cyanobacteria during the 1980s and early 1990s, particularly a 1,000-km long bloom on the Darling River. In estuaries the study which greatly enhanced understanding and served to stimulate further research into estuarine eutrophication, the Port Phillip Bay Study, was initially designed to address perceived problems of toxicants in the Bay but provided profound insights into drivers for, and ecosystem responses to, eutrophication. Subsequent estuarine research has largely been stimulated by management questions arising from Australia's increasing coastal development for residential purposes. The research has shown that some of the beliefs extant at the time of the blooms were incorrect. For example, it is now clear that stratification and light penetration, not nutrient availability, are the triggers for blooms in the impounded rivers of south eastern Australia, although nutrient exhaustion limits the biomass of blooms. Again, nitrogen seems to play as important a role as phosphorus does in controlling the biomass of these freshwater blooms. The research has also shown that aspects of eutrophication, such as nutrient transport, are dominated by different processes in different parts of Australia. Many of the biophysical processes involved in eutrophication have now been quantified sufficiently for models to be developed of such processes as sediment–nutrient release, stratification, turbidity, and algal growth in both freshwater and estuarine systems. In some cases the models are reliable enough for the knowledge gained in particular water bodies to be applied elsewhere. Thus, there is now a firm scientific foundation for managers to rely upon when managing algal blooms.

Sources of nutrients

Although some waters are naturally eutrophic, enrichment from nutrient sources, and accelerated consequential impacts, can occur because of human activities.

Nutrient sources are either *point* sources or *diffuse* sources.

Point sources include:

- Effluent from sewage treatment works
- Industrial effluents
- Fish farms

Diffuse sources include:

- Fertilizer, livestock manure and sludge applied to land
- Overflows from septic tanks and leakage from sewers

Most attention has been paid to tackling point sources, such as sewage treatment works, since this has proved easier than tackling diffuse sources. However, as directives are put in place to tackling sewage treatment inputs to areas of conservation importance, diffuse sources are receiving more attention.

What constitutes a point or diffuse nutrient source is not always obvious. For example, atmospheric deposition and agriculture are classed as diffuse sources, as is urban runoff, but sewage treatment works are classed as point sources, even though a proportion of the nutrient load to them is diffuse in origin. Human waste to rivers via sewage treatment works is regarded as a point source, but this is derived from a population that occupies the same area from which “diffuse” urban runoff is derived. In agriculture, a significant proportion of the pollutant load is generated from small point sources, such as a farmyard. In an agricultural context, the categorization of nutrient loads into point and diffuse sources is largely a scale issue, with small point sources regarded as diffuse pollution on a catchment scale, but increasingly as point sources as the spatial resolution of observation increases. Nutrient enrichment of inland and tidal waters is considered by the European Environment Agency to be one of the most important issues to facing Europe. However, this enrichment is heterogeneously distributed both throughout Europe and within the UK. On a national and European basis, diffuse source-derived P is typically estimated to constitute some 40–60% of the surface water nutrient budget, while diffuse source-derived N accounts for approximately 70–80% of the nitrogen load. In groundwater, a higher proportion (often >95%) of the nitrogen budget is derived from diffuse sources.

Effects of nutrient enrichment

The consequences of enhanced growth of freshwater phytoplankton stimulated by nutrient enrichment include:

- Effects on water quality caused by algal blooms; these include disturbing changes to a lake’s appearance and smell as a bloom grows or decays, and the release of colored organic compounds and toxins into the water – the latter is a particular problem if the lake is a drinking

water reservoir, because the toxins are not always removed by standard potable water treatments.

- Increased hypolimnetic deoxygenation (as enhanced organic production sinks into deeper water) and consequential effects on benthic animals and fish living near the lake bed.
- More general effects on lake food webs, such as those resulting from increased dominance of chain-forming cyanobacteria which zooplankters find noxious or difficult to ingest.

Sometimes there has been explicit or unintentional confusion of the effects of plant nutrient enrichment and the effects of BOD addition (and the oxygen-consuming decay of organic material releasing nutrients which secondarily stimulate more organic production). The first can lead to the production of extra organic matter which consumes oxygen when it decays. The second involves the oxygen-consuming decay of organic material, which can release mineral nutrients which secondarily stimulate more organic production.

As argued by Lund (1972), it is best to restrict the term “eutrophic” to effects stimulated by plant nutrients. The distinction between *allochthonous* (external) and *autochthonous* (local) production is useful. BOD is the result of allochthonous production; nutrient enrichment stimulates autochthonous production.

Overgrowth and oxygen deficiency

Urban and industrial emissions of wastewater were one of the first environmental problems to become universally apparent. They were already causing problems in the UK at the beginning of the twentieth century, in the form of “stenches, filth, and infection.” Their abundant content of *organic material* was gradually broken down by microorganisms in the water, but degradation of this kind consumes oxygen, producing knock-on effects in the form of oxygen deficiency and fish kill.

Vegetation densified along banks and shores, plankton algae became increasingly abundant, and dead plants and animals accumulated in ever-thicker benthic layers. In this way, the polluted lakes and coastal inlets gradually silted up, and the open expanses of water grew smaller. Lake overgrowth is partly a natural process which has been going on ever since the lakes were formed after the glacial period. But the anthropogenic eutrophication of recent years has drastically accelerated the process in many places.

Elimination of species

The effects of a moderate eutrophication of originally nutrient-poor water are not entirely negative. Increased growth of algae and other vegetation can be beneficial to the aquatic fauna, at least to begin with. Fish production rises, for example. If, on the other hand, eutrophication continues, plankton growth becomes so heavy as to cloud the water. The resultant darkness below the surface is harmful to the benthic vegetation. The process favors

plankton-eating “coarse fish” like the roach and bream, while depleting the numbers of the predator fish species more sought after for human consumption.

In highly nutrient-rich waters, plankton production can be copious. Certain plankton species appear intermittently in massive quantities. These are called *algal blooms*. Such algae can give the water an unpleasant smell or taste, and some are even poisonous. Intensive algal production has the same consequences as if the water had received organic material from a pollution source: a large part of the oxygen content of the water is consumed when these masses of plankton die, sink to the bottom and are degraded. Oxygen deficiency can eliminate benthic life and sometimes fish as well. If the benthic water becomes completely de-oxygenated, hydrogen sulfide – toxic to all higher forms of life – is formed instead.

Heavy eutrophication entails a distinct reduction in the number of plant and animal species in the water. A few species benefit, but at the expense of all the others.

Drinking water supply

Excessive algal growth in raw water reservoirs can cause severe problems with water treatment and supply. With the predicted global warming trend, problems of this nature could become more frequent and acute. The implementation of effective measures to control the problem will take on increasing importance. Several immediate measures exist to control the excessive growth of algae or other aquatic plants. Practical control measures include:

- The corraling and removal of algal scums
- Destratification
- Weed-cutting and removal
- Barley straw application
- Biomanipulation techniques which alter the fish community

These measures are described in more detail in the section on *Reservoir Management*. The effects of these measures are often temporary and reversible.

In the longer-term, the direct control of external nutrient sources includes:

- Removal of nutrients from sewage effluents
- Targeted farm advisory visits in which nutrient and waste management plans are drawn up
- Treatment of fish farm effluents
- Treatment of urban and highway run-off

Control of internal nutrient loadings can also form an important step in the restoration of waters affected by eutrophication. Potential control measures include:

- Flushing with low nutrient water
- Removing nutrient-rich sediments by suction dredging
- Aerating the lower layers of a stratified water
- Removing nutrients by harvesting of biomass

Water treatment problems

Growth of algae in raw water reservoirs can cause problems for water treatment and supply, in relation to:

- Rapid blockage of filters, causing short filter runs and reduced throughput and/or increased volumes of wastewater from backwashing
- Increased dissolved organic carbon (DOC) in treated water from algal polysaccharide, which can result in customer complaints and increased chlorination by-product concentrations
- Penetration of algae through filters
- Taste and odor problems
- Production of toxins

Examples of common water treatment problems associated with algal types are given in [Table 2](#).

The most common cyanotoxins produced by blue-green algae in European waters are microcystins and anatoxins. The World Health Organization has set a drinking water provisional Guideline Value of 1.0 µg/L for microcystin-LR, one of the most commonly occurring cyanotoxins. These toxins can occur within algal cells (intracellular or cell-bound toxin) or be released from cells to the surrounding water (extracellular toxin). An algal bloom with 100,000 *Microcystis* cells per mL could contain 20 µg/L microcystin.

The production of the taste and odor compounds geosmin and methyl isoborneol (MIB) is known to occur by many blue-green algal species in rivers and, more significantly, reservoirs used for water supply e.g., *Oscillatoria*, *Microcystis*, *Anabaena* and *Aphanizomenon*. The musty taste and odor from these compounds in drinking water is detectable at very low concentrations of less than 10 ng/L. Like cyanotoxins, geosmin and MIB can occur in both intracellular and extracellular forms. Algal cells can contain, for example, concentrations of 10⁻⁵ ng/cell, so a relatively small algal bloom of 10,000 cells/mL would produce levels of 100 ng/L.

Eutrophication in Fresh Waters: An International Review, Table 2 Examples of water treatment problems associated with algae

Algal class	Example genera	Water treatment problems
Cyanophyceae (Blue-green algae or cyanobacteria)	<i>Anabaena</i> , <i>Aphanizomenon</i> , <i>Microcystis</i> , <i>Oscillatoria</i> .	Filter blockage, taste and odor, toxic metabolites (cyanotoxins).
Chlorophyceae (Green algae)	<i>Chlorella</i> , <i>Scenedesmus</i> , <i>Spirogyra</i> .	Taste and odor, filter blockage.
Bacillariophyceae (Diatoms)	<i>Asterionella</i> , <i>Fragilaria</i> , <i>Melosira</i>	Taste and odor, filter blockage.

Prevention of algal problems in drinking water may require catchment management to prevent ingress of nutrients to water sources, reservoir management to remove nutrients or inhibit algal growth, or the installation of suitable treatment regimes to remove algal cells and their metabolites.

Catchment management

One of the key causative factors for algal blooms in reservoirs and rivers is nutrient concentration, particularly phosphate. Catchment management measures therefore aim to prevent excessive nutrient input. Monitoring for changes in nutrient input from point or diffuse sources, arising primarily from sewage discharges (including septic tanks and cesspits) and agriculture should be in place to identify an increased risk of blooms. Many of the factors of importance in catchment protection are outside the direct responsibility of the Water Industry and catchment management therefore relies on effective liaison with other organizations to promote good practices. Many reservoirs and feeder streams may already contain nutrient concentrations well above the threshold for algal

growth and further control of nutrient input will therefore have minimal benefit. In these circumstances, the emphasis would need to be on reservoir management to control algal blooms rather than catchment management.

International practice has shown that the best examples of success in treating eutrophication are from diversion of wastewater. Lake Washington is a good example of catchment management. Figure 3 shows declining phosphorus concentrations in this lake after diversion, which was completed in 1967.

Lough Neagh (Figure 4) is the UK's largest lake and a multipurpose resource. The Lough is a major source of drinking water and one of the most eutrophic lakes in the world due to high phosphorus (P) inputs. The P inputs to Lough Neagh have been measured and ascribed to point sources. Phosphorus from sewage works was shown to account for almost half the amount entering the lake. To curtail this source, P reduction treatment was introduced in 1981 at the ten major sewage disposal works in the Lough Neagh catchment. This was the first time P reduction treatment had been employed in the UK and it led to a reduction in P loading and improved water quality in the lake. Lough Neagh and its tributaries have been sampled at least fortnightly since 1969 and the unbroken record of nutrient inputs and water quality in the lake shows that in the early 1990s, the effects of sewage P reduction were overtaken by increasing diffuse P loads.

Reservoir management

Reservoir management strategies can be either reactive or proactive in relation to algal growth. Reactive management in response to increased algal levels is limited to changing draw-off levels or moving the point of abstraction (if possible). Proactive control is aimed at preventing or minimizing algal blooms, including:

- *Destratification/aeration*; stratification of deeper reservoirs enhances algal growth in the warmer upper regions (epilimnion), and can cause other water quality problems as a result of low dissolved oxygen concentration in the colder deeper water (hypolimnion). A range of mixing or aeration techniques, often proprietary, has been developed to prevent stratification or provide aeration of the hypolimnion.
- *Use of barley straw*, which decomposes to release compounds that inhibit algal growth. This is currently exempted from the EU Biocidal Products Regulations but only until 2008; unless the mechanism can be clarified it may be banned.
- *Nutrient removal by plants* (e.g., reed beds, willow), situated around or at the inlet to the reservoir.
- *Chemical stripping of phosphate*; historically this has used salts of iron or aluminum, already used as coagulants in water treatment, but new technologies are available, such as "Phoslock," a proprietary material developed in Australia and applied in a pelletized form to incorporate phosphate and make it unavailable for algal growth.

- *Chemical dosing of algicides*; copper salts are used in some countries but this is not always permissible, because of its environmental impact.
- *Biological control*, using microorganisms which are pathogenic to algae or by manipulation of the animal populations within the algal food chain.
- *Ultrasound* for disruption of algal cells.

Some of these can also be reactive in relation to destroying existing blooms. The performance and acceptability of each approach will depend upon characteristics of the reservoir (e.g., size, depth), the nature of the water (e.g., hardness) and the other uses of the reservoir. Some of the techniques are well established but others, such as ultrasound and biological control, have yet to be widely demonstrated at the scale of water supply reservoirs. For many of these control techniques there will be regulatory implications and approval of, or liaison with, the appropriate environmental organizations would be needed.

Water treatment

Conventional water treatment using chemical coagulation can remove algal cells (and intracellular or cell associated products) but is largely ineffective for removing extracellular toxins or taste and odor compounds. These require more extensive treatment using, for example, activated carbon or oxidants such as ozone. Some treatments, particularly using oxidants, can break down algal cells and release toxin or taste and odor compounds, and care is therefore needed in operating these processes to avoid creating additional treatment problems downstream. Concerns over by-product formation need also to be taken into account in any treatment strategy using oxidants.

A number of approaches can be used to reduce treatment problems directly associated with the load of algal solids. These include:

- Pretreatment using microstrainers or flotation to reduce algal loads to the main treatment units
- Modification to the coagulation conditions to improve removal or reduce coagulant/algal solids loading
- Use of an oxidant prior to coagulation to enhance its performance
- Use of alternative filter media, such as dual media or multi-media, principally to increase filter run lengths
- Use of prefilters or polishing filters

Ozonation is highly effective for cyanotoxin degradation. Oxidation using potassium permanganate is also effective but relatively high doses may be needed for application to raw waters rather than to part-treated water within the treatment process. Chlorination under typical water treatment conditions is effective for microcystins but not for anatoxins. Low doses of oxidants to raw water can increase the concentration of extracellular cyanotoxin as a result of cell lysis.

Activated carbon adsorption is moderately effective for both microcystin and anatoxin, and removal by granular activated carbon (GAC) can be enhanced by biological

activity in the bed. Performance is dependent upon the type of carbon. For powdered activated carbon (PAC), wood-based types are the most effective but even for these relatively high doses (>20 mg/L) may be needed.

Biological activity in slow sand filters may give some removal of extracellular cyanotoxin, although there is little firm evidence for this. Use of a GAC layer within the sand, applied at some works for pesticide removal, could be used to give more reliable removal.

Of the oxidants used in water treatment, only ozone is effective for geosmin and MIB removal, although relatively high doses can be needed. Geosmin is more readily oxidized than MIB and is also more amenable to removal by activated carbon. GAC can be effective for taste and odor removal, even at relatively short empty bed contact times. However, longer contact times of 15 min or more can enhance removal by increased biological activity. Doses of PAC needed for geosmin and MIB are similar to those required for cyanotoxin removal.

Monitoring

It is important to have an effective algal monitoring strategy in place for control of reservoir and treatment management regimes. Monitoring and management of large reservoirs can be highly demanding in relation to cost and staff time, and monitoring technology may have an increasing role in future to help make best use of often limited resources. Instruments are available based on fluorescence measurement of pigments, which may indicate the predominant algal types and the nature of the risk to treatment, from the fluorescence profile. A hierarchy of monitoring procedures can be identified, ranging from routine visual inspections of the reservoir through to laboratory analysis for toxins, with the objective of identifying increased risk of cyanotoxin bloom formation and managing the risk through increased levels of monitoring and appropriate operational actions.

Case study examples of eutrophication and water quality management

The International Lake Environment Committee (ILEC), in cooperation with the United Nations Environment Programme (UNEP), undertook a project entitled "Survey of the State of the World Lakes." This aimed to collect and compile environmental data on many important lakes of the world. Sets of detailed data from 217 lakes worldwide were gathered as a result of this project – it was possible to identify six major environmental problems, all having a significant impact on water quality, eutrophication being one of them. In addition, all six environmental problems are interrelated and to a certain extent compound the problems. All are caused by the same three basic factors (Figure 5).

All 217 lakes included in the ILEC survey showed an increase in the level of eutrophication over the past 50 years. For a number of lakes in industrialized countries, wastewater treatment to remove nitrogen and/or phosphorus has stopped water-quality degradation. By 2000 nutrient inputs

Eutrophication in Fresh Waters: An International Review, Figure 5 The basic factors which cause environmental problems in lakes and reservoirs.

to 66 world lakes were reduced. Even so, most are still more eutrophied (nutrients concentration is higher) today than they were 50–60 years ago. This is so for Lake Biwa in Japan, Lake Constance on the border between Germany, Switzerland and Austria, Lake Balaton in Hungary, Lake Mälleran in Sweden, the Great Lakes in North America and a number of North European lakes. Some case study examples are described in the following sections.

Lake Victoria, Uganda

The water hyacinth, *Eichhornia crassipes*, is a flowering plant with a native range in the Amazon areas of South America. It is one of the main exotic aquatic weeds (the other is *Salvinia molesta*) to have invaded East African freshwater ecosystems in the last decades. Although the presence of water hyacinth in Lake Victoria was reported in 1989, it is suspected that the weed may have gained entry to the lake via the Kagera River (from Rwanda) as early as 1981 (Taylor, 1993). Therefore the spread of water hyacinth in East Africa, particularly in Uganda, may have been from several sources.

In Lake Victoria (Figure 6), water hyacinth is especially concentrated in Ugandan waters, partly because the prevailing southerly winds blow mats from the mouth of the Kagera River. Increased nutrient loads into the lake also seem to have spurred water hyacinth infestations, particularly in bays receiving municipal sewage. There are several modes of hyacinth mats occurring in Lake Victoria. These include: Mobile mats; resident shoreline fringe mats; rooted colonies; successional forms found in association with other wetland plants; and mat concentrations in nutrient-rich habitats. The location, size, and form of water hyacinth mats are therefore highly variable, with some mats reaching 300 ha in cover, others infesting entire bays or drifting about the lake. The main negative effects of the increasing infestations of water hyacinth mats are:

Eutrophication in Fresh Waters: An International Review, Figure 6 Water Hyacinth in Lake Victoria, Uganda.

- An apparent reduction in fish population caused by smothering of breeding grounds, extensive deoxygenation in some areas, and increased debris loads over feeding grounds

- An increased habitat for disease vectors (*Biomphalaria* bilharzia snails), mosquitoes, snakes, etc.
- An alteration of the natural wetland fringe through successional patterns, and elimination of underwater plants and enhydrophytes in general

There are also a variety of socio-economically detrimental effects of water hyacinth. These include:

- Physical threats to water-based utilities, especially the national hydroelectric power station in Uganda, and to water intakes, in addition to increased operational costs for purifying and pumping the water
- Physical interference to water supply for rural communities
- Physical interference with fishing operations (entanglements or loss of nets), especially in fishing grounds, at fish landings, and around piers
- Blockage of commercial transport routes and communications between islands
- Increased operational costs for commercial vessels

Controlling water hyacinth on Lake Victoria and preventing its spread to other water bodies involves intergovernmental agencies and requires regional cooperation. Various control options exist (physical/manual, mechanical, chemical, biological, utilization, and environmental manipulation), but identifying the most efficient, viable and environmentally friendly option combination for Lake Victoria remains elusive. Manual and mechanical control measures have had little impact. Biological control may be regarded as a viable but expensive option and takes many years to show impact.

Although the use of chemicals to control the weed has been used in some countries, there are reservations about its perceived environmental, socioeconomic and political implications. In considering the option, fears have been expressed regarding the contamination of water for domestic and livestock use of the rural communities living close to the lake.

A solution to eutrophication in the developing countries is urgent since stopping eutrophication becomes more and more difficult and expensive every year it is postponed due to increasing nutrient accumulation in sediments.

Lake Biwa, Japan

The eutrophication of Lake Biwa began in the 1960s when the postwar economic growth of Japan began. The plant biomass concentration in the 1980s was about 10 times than that in the 1950s. Thirteen million people depend on the water supply from the Lake Biwa/Yodo River system. Since 1969, unpleasant odors in tap water from Lake Biwa have annoyed users every summer.

Plankton biomass peaked in the late 1970s, when blooms of red algae also appeared as a "freshwater red tide." This has occurred almost annually since then. Blooms of blue-green algae have appeared since 1983, a sign of more advanced eutrophication.

Trends in the degradation of water quality in Lake Biwa have now more or less leveled off, following cooperative

efforts of the residents and local government of Shiga Prefecture. Advanced wastewater treatment was introduced. The use of detergents based on polyphosphates was banned. And wetlands were constructed to cope with drainage water from agriculture. As a result of these measures, the degradation of water quality stopped, but no signs of further improvements have yet appeared. A more extensive abatement of diffuse pollution is probably needed before water quality improves significantly.

Lake Fure, Denmark

Lake Fure is a typical example of water management in Northern Europe. As in many other European lakes, the eutrophication of Lake Fure began in the 1960s. Lake Fure is situated only 15–20 km from Copenhagen in an attractive area with several lakes and forests. The population close to Lake Fure was therefore growing in the decades after the Second World War, with increased impact on the nature in the area, including lakes. At the start of the century, the transparency of the lake water was several meters, while in the late 1960s it was only 1.2 m during the spring and summer blooms.

In the early 1970s it was decided to expand treatment of the wastewater from about 30,000 inhabitants to include nutrient removal (98% removal of phosphorus). Wastewater from another 100,000 inhabitants was diverted to the sea. By these measures the phosphorus loading was reduced from 33 to 2.5 t per year. The remaining phosphorus loading comes from storm water overflow, from the treated wastewater and from diffuse sources.

As a result of these efforts, the transparency has almost doubled since the late 1960s. However, the lake has a water retention time of 20 years, which explains why even larger improvements have not yet been observed. Only a little more than 20 years have passed since measures were commenced, and 2–4 retention times are usually needed to see the full effect of the measures taken. While, the external phosphorous loading (mainly wastewater) has been reduced to 2.5 t/year, the internal loading, i.e., the loading from the sediment is still about 12 t/year. Consequently, other methods have been considered to restore the lake. However, on a long-term basis, it is still beneficial to reduce external loads of phosphorus to less than 1 t/year. This can be done by proper treatment of storm water overflow, and by increasing phosphorus removal efficiency by the wastewater treatment to 99% or more. In Lake Fure, diffuse pollution is less important, as the lake is more or less surrounded by wetlands and forest.

Extensive wastewater treatment involving nutrient removal has been introduced for many lakes in northern Europe, but, as Lake Fure shows, a long time will elapse before the full effect of this treatment can be observed. In addition, further reduction of nutrients is needed before an adequate reduction in eutrophication can be expected. In most cases nonpoint (diffuse) source pollution will be needed to be reduced considerably – clearly a much more difficult task than reducing point source pollution.

North American Great Lakes

Approximately 30% of Canada's population and 20% of the US population live in the Great Lakes drainage basin, some 520,000 km². The Great Lakes comprise: Lake Superior, Lake Michigan, Lake Ontario, Lake Erie and Lake Huron. 24 million people depend on these lakes for drinking water. Industrial growth in the 1940s and 1950s resulted in oil pollution and eutrophication accelerated in the 1960s. By the late 1960s, water quality had deteriorated to a critical level. Massive algal blooms were frequent, and severe oxygen depletion occurred, even in the central bottom water of Lake Erie. Massive fish die-offs took place in Lake Michigan and Lake Ontario.

In response to this situation, specific effluent standards were established in the early 1970s. Phosphorus removal was introduced in wastewater treatment plants, and phosphorus content in laundry detergent was reduced from 30–40% to 5%.

By the early 1980s, the phosphorus loading approached the target established 10 years earlier. In Lake Erie and Lake Ontario, it was reduced by 20%, but overall the reductions in the Upper Great Lakes were only about 50%. These reductions were also reflected in the total phosphorus concentrations and phytoplankton concentrations in the open water of Lakes Erie and Ontario. These reductions were only to about one third of the 1970 peak values. Again, reductions of non-point sources of phosphorus and nitrogen to the same extent as for municipal wastewater were not possible. However, measures to abate eutrophication of the Great Lakes are among the most successful lake management case studies, because point source pollution was the major source of nutrients discharged to the lakes.

Preventing eutrophication – European directives

In addition to local eutrophication control, the European Commission has adopted legislation, which applies to all Member States in the European Union, for the control of eutrophication either directly or indirectly at a national level. The relevant Directives, which all aim to limit pollution, are described below:

- The Urban Waste Water Treatment Directive

This Directive sets minimum standards for the provision of sewage collection and treatment. Discharges of greater than 10,000 population equivalent to waters identified by Member States as sensitive to eutrophication – termed “Sensitive Areas (Eutrophic)” – must comply with specified standards for phosphorus and/or nitrogen (depending on the situation), in addition to a requirement for secondary sewage treatment.

- The Nitrate Directive

This Directive has an objective to “reduce water pollution by nitrates from agricultural sources, and to prevent further such pollution.” A water body is identified as polluted if it shows signs of eutrophication – induced

by excess nitrates – or if it is used for drinking water abstraction and has elevated concentrations of nitrate.

- The Habitats Directive

This Directive enables the designation of Special Areas of Conservation (SACs) in which rare and endangered habitats and species must be protected. If eutrophication threatens the conservation status of such areas there may be a need to impose nutrient control requirements on discharges, where appropriate. The environment regulators have a duty to review discharge consents to ensure that the designated sites are adequately protected.

- The Wild Birds Directive

This Directive gives the same protection against discharges to sites designated as Special Protection Areas (SPAs).

The Water Framework Directive incorporates the requirements of the existing Directives, supplemented by whatever additional measures are needed to control pollution sources, both point and diffuse, to achieve the stated objective. It is therefore an essential vehicle for the control of eutrophication, providing a coordinated approach to sustainable water management through river-basin management plans, assessing the state of waters and the sources of pollution, then formulating and implementing improvement plans. The objective is to achieve good ecological quality, which will include avoidance of the effects of eutrophication.

In addition to the EC Directives, there is a range of international commitments, elements of which are of direct relevance to eutrophication control:

The Earth Summit Conference in Rio de Janeiro in 1992 resulted in the UK entering into commitments to safeguard the well being of the planet. A UK Biodiversity Group has been set up to take forward the Government's commitments to preventing the loss of species and habitat, under the UK Biodiversity Action Plan. Action Plans for priority habitats and species are being developed including those to protect mesotrophic lakes and eutrophic standing waters where control of eutrophication will be important in maintaining or restoring biodiversity.

The identification and control of diffuse agricultural sources of nutrients present the greatest challenges. There are increasing pressures on the agricultural industry to develop more environmentally sustainable farming methods. In England and Wales this is being implemented through agri-environment schemes where grants are offered for farming in a more environmentally sympathetic manner.

Preventing eutrophication – public awareness and education

The few, partial success stories concerning eutrophication abatement have all involved strong public support by communities and stakeholders combined with effective legislative measures and monitoring programs. The best results were obtained when control measures began early and long before hyper-eutrophication occurred. Generally,

problems involving point sources were relatively easily solved, while those involving nonpoint diffuse sources were more difficult to resolve.

Although water authorities can construct wastewater treatment plants with adequate nutrient removal, a constant awareness about water quality can only be maintained by public engagement. The final reduction of nutrients to a lake requires effective reduction of diffuse sources and this must involve the wider community. For full success, community residents must be partners in the environmental management strategy.

Using less detergents and detergents with no or little polyphosphates can reduce phosphorus loads considerably. A campaign in Poland to reduce phosphates from laundry was aimed at the whole Polish population and was very successful. The phosphorus loading in many towns and villages fell by more than 20%. The results of the campaign were monitored to encourage stakeholders to continue efforts. The campaign also increased the general environmental awareness of the public and made them aware of the direct effects of laundry detergent on eutrophication.

Reduction of nonpoint pollution in areas with extensive agriculture requires the construction of wetlands as a buffer between fields and rivers and lakes. This is, however, not sufficient of itself, but must be supported by a massive campaign to persuade farmers to use less fertilizers. The final 10–20% of fertilizers applied has almost no effect on agricultural yield, but can contribute significantly to nutrient concentrations in drainage water. A campaign in Denmark in the early 1990s resulted in some reduction of diffuse pollution, probably because the farmers calculated that they saved money by reducing fertilizers. The reduction, however, was not sufficient – a green tax on fertilizers was considered but has not yet been introduced.

Active participation by communities in abating eutrophication is impossible without their understanding of the problem. This requires environmental education of communities. In many industrialized countries a number of leaflets and booklets on environmental information are distributed free to the public. These give information needed by citizens to enjoy their environment and to take an active part in the debate.

In 1987, UNESCO defined environmental education as follows:

Environmental education is a permanent process in which individuals gain awareness of their environment and acquire the knowledge, values, skills, experiences and also the determination which enable them to act – individually and collectively – to solve present and future environmental problems. It is therefore a continuous, lifelong process.

Glossary of terms

Anoxia, anoxic conditions No oxygen present.

Bio-manipulation Change in biological structure by removing and/or stocking living organisms.

Chlorophyll a The green pigment in plants that promotes photosynthesis.

Epilimnion See *Thermocline below*.

Eutrophic Nutrient rich.

External loading Nutrients from outside the lake, for instance nutrients in wastewater discharge to the lake, or nutrients from agricultural drainage water.

Hypolimnion See *Thermocline below*.

Internal loading Nutrients from the lake itself, for instance release of nutrients or toxic substances from the sediment (the muddy bottom layer) of the lake.

Mechanical-biological treatment Treatment of wastewater by settling of suspended matter together with the use of microorganisms to decompose organic matter. Only minor amounts of nutrients (nitrogen and phosphorus) are removed by this treatment.

Nonpoint source (diffuse) pollution Pollution mainly from agriculture or dumping grounds. It is difficult to collect for treatment.

Photosynthesis Formation of plant biomass from nutrients with solar radiation as the energy source.

Phytoplankton Free-floating microscopic plants.

Point source pollution Polluted water from a defined point. It can be collected as industrial or municipal wastewater and treated by what is often called end-of-pipe technology (environmental technology).

Sediment The bottom and often muddy layer of a lake.

Thermocline The level dividing a lake into two layers, an upper warmer one (epilimnion) and a lower colder one (hypolimnion). The temperature usually drops several degrees centigrade over just a few meters at this level.

Zooplankton Microscopic to very small free-floating animals.

EVERGLADES, FLORIDA, USA

Fred H. Sklar¹, Thomas D. Fontaine²

¹Everglades Division, South Florida Water Management District, West Palm Beach, FL, USA

²Western Ecology Division, US EPA, Corvallis, OR, USA

Introduction

The “river of grass” label often attributed to the Everglades (Douglas, 1947) still holds true in many parts of this impressive subtropical wetland system, and is clearly visible to those who have flown over South Florida. From

the ground, the river of grass is also apparent but the distinctive landscape patterns are less easily detected. In reality, the Everglades landscape contains a multitude of wetland types including sawgrass (*Cladium* spp) marshes, sloughs, marl- and peat-based wet prairies, tree islands, pinelands, and, at its southernmost extreme, mangroves and the Florida Bay estuary. Before major human influence, the Everglades landscape was even more diverse and included custard apple swamps, short-hydroperiod wet prairies, and cypress strands (Davis et al., 1994).

Access to this wetland system is difficult. Airboat travel is the norm, and aside from the limited geographical area covered by tourist concession airboats, few venture deep into the interior wetlands. Once there, however, the visitor is welcomed by a plethora of intriguing biological utterances, magnificent but greatly diminished wading bird populations (Ogden, 1994), occasional bellowing alligators, sometimes searing heat, and, depending on the area and season, biting and sucking insects of impressive numbers and noise.

At one time, the Everglades covered about 1.2 million hectares, extending south from Lake Okeechobee to the peninsular tip of Florida, east to the coastal ridge (with occasional connections to the sea through areas known as the transverse glades), and west to the Immokalee Ridge (roughly the border of the Big Cypress National Preserve). An area of 283,290 ha immediately south of Lake Okeechobee that was once sawgrass marsh is now, however, dominated by agricultural uses (primarily sugarcane). Additional areas along the eastern border of the Everglades that were once cypress stands are now urban areas. This loss of about half of the original Everglades wetland area has resulted in a loss of habitat diversity, including that required for wading bird foraging, a reduction of total areal productivity, and a loss of three major vegetation communities.

Formation of the Everglades occurred largely in recent geological time, about 5,000 years ago. Water historically flowed slowly in a southerly direction from Lake Okeechobee to Florida Bay, creating conditions favorable for development of an underlying peat deposit that is one of the world's largest. In the late nineteenth century, construction of canals was initiated to drain the Everglades to make it suitable for agriculture. About a century later, thousands of kilometers of canals and levees had been built, providing not only land for agriculture but also accomplishing flood control and water supply objectives. What resulted from these canals and the large pumps that move water through them, collectively known as the Central and Southern Florida (C&SF) project, was lowered water tables, altered hydropatterns, and transport of vast quantities of freshwater to the ocean that would have naturally flowed down the Shark River and Taylor Sloughs into the Gulf of Mexico and Florida Bay (Light and Dineen, 1994). A system once characterized by hydrological sheet flow had become a highly compartmentalized and regulated system.

High phosphorus concentrations in Lake Okeechobee and excess nutrient runoff (eutrophication) from the Everglades Agricultural Area (EAA) have contributed to shifts of vegetation communities in the Water Conservation Areas (WCAs) from sawgrass to cattail. Nutrient runoff from the EAA has resulted from fertilizer application and through oxidation of the peat soils due to agricultural water management practices. Oxidation and other factors have led to an average annual soil subsidence rate of approximately 2.5 cm. In the EAA this has led to more than 2 m of soil loss since the first canals were dug in the 1920s (Sklar et al., 2005). Eutrophication and changed hydropatterns have altered the extent and coverage of naturally occurring fires, and have provided areas more suitable for successful invasion of exotic species such as *Melaleuca* and *Casaurina*. *Melaleuca* presents a significant problem because of its potential to spread, its ability to outcompete native vegetation, and its high evapotranspiration potential. The latter could have a significant impact on the water budget of South Florida and the ability to satisfy water demands by urban, agricultural, and natural systems.

Although there is little disagreement that the Everglades have been regrettably altered during the last century, there is considerable discussion about what a restored system should look like. Should it be based on the vegetation patterns that existed before human influence? Were these patterns constant or constantly changing? What hydropattern and nutrient levels would be conducive to restore the landscape? Because half of the Everglades has been lost to agriculture and urban uses, should the restoration goal be to reproduce the original Everglades in half the space? Alternatively, should restoration efforts return the Everglades that remains to short-hydroperiod wetlands that existed on the edges of the original Everglades? In addition, can sufficient restorative water be sent to Florida Bay through the extant Everglades without adversely affecting upstream hydropattern restoration efforts?

Determining how to accomplish an Everglades restoration while sustaining agricultural and urban systems of South Florida is the subject of intense debate and the focus of major scientific and engineering programs. The first big step was implementation of best management practices (BMP) in the EAA and in the watershed tributaries of Lake Okeechobee. The second big step was the construction of about 25,000 ha of ecologically engineered wetlands called Stormwater Treatment Areas (STAs) for reduction of EAA phosphorus runoff. The combination of BMPs and STAs, as well as future nutrient reduction

technologies, is intended to achieve reductions in phosphorus loads and concentrations that will protect the Everglades from imbalances of flora and fauna.

The Comprehensive Everglades Restoration Plan (CERP), approved jointly by the U.S. Congress and Florida in 2000, created additional restoration efforts with a focus on identifying historical hydropatterns, hydrology needs of the Everglades, and engineering solutions to achieve the needed water distribution, depth, and timing of delivery. CERP is expected to first “decompartmentalize” the Everglades, which is divided into five “compartments” by a system of canals and levees that prevent water from moving freely across the landscape. These compartments produce excessive dry downs that cause tree island and peat fires in their upstream reaches and excessive flooding that cause tree island degradation and habitat loss in their southern reaches. Downstream of these five compartments and separated from them by the old Tamiami Trail Road is the Everglades National Park. The restoration of the hydrology of this park will depend upon the designs that are selected for the raising and lifting of Tamiami Trail, the identification of new sources of water, and the management of groundwater seepage from the park into flood-prone residential areas.

F

FENS, ENGLAND

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

The Fens are unique with a history and character all of their own. This area of England fans out from the Wash across Cambridgeshire, Lincolnshire, and West Norfolk, UK. Once an inhospitable swampy wilderness, the Fens have been tamed to leave us today with a network of intricate waterways, which are renowned as some of Britain's most atmospheric and tranquil.

An immediate problem in providing any brief summary of fens is that ecologists themselves differ in how they use the term. Firstly it is necessary to distinguish “fen” as an ecological term from “Fenland” as a geographical entity.

Fenland, a geographical area of East Anglia

Geographically, Fenland is the ancient area of marshes on the vast floodplain that surrounded the rivers Witham, Welland, Nene, and Ouse (and their subsidiaries) that drain much of central and eastern England and flow into the Wash between Norfolk and Lincolnshire. It is or was an area of several hundred square miles (3,800 km²) and, in postglacial times, evidently continued much further still into what is now the North Sea. It extended from Lincolnshire in the north to Norfolk in the southeast, encompassing much of the geographical (no longer political) country of Huntingdonshire and part of Cambridgeshire.

Perhaps one indication of the immensity of the area is the myth and legend surrounding Hereward the Wake, an ancient “Robin Hood-like” folk hero or outlaw who operated out of the Fens and who fortunately has not yet been

subjected to the same recent historical and cultural media travesties as Robin Hood.

Little of this ancient area now exists. Most is now arable farmland, a flat landscape of huge fields and drainage dyke, with few natural hedges and with scattered, surprisingly isolated human communities. A few fragments remain to provide most of our finest British examples of “fen” as an ecological concept. These include Chippenham Fen and Wicken Fen in Cambridgeshire, and Holme and Woodwalton Fens in Huntingdonshire, all of which are National Nature Reserves, though Wicken Fen, the most accessible of these, is owned and managed by the National Trust.

Though outside Fenland as defined here, there are a number of named fens stretching further east in Norfolk across to the Norfolk Broads, generally as parts of valley mire complexes. Many of the fenland rarities are or were to be found in both areas.

Fens as an ecological concept

Ecologists regularly use the word “fen” but establishing a precise definition is more difficult, reflecting the diversity and continuity of habitat and vegetation types. Generally, however, use of the term equates to the majority of *topogenous mires*, where local relief results in permanently high water tables, as on flood plains and in shallow depressions, or in transitional zones of vegetation bordering open waters. Smaller areas of fen may also occur within *soligenous mires* associated with routes of moving drainage water. It is understood here that any type of mire is generally characterized by peat formation, i.e., the buildup of incompletely decomposed organic matter under conditions of waterlogging and negligible diffusion of oxygen, though in fact some soligenous fens accumulate little or no peat, though are otherwise similar in hydrochemistry and vegetation.

The East Anglian fens are characterized by alkaline conditions resulting from water draining from chalk and other calcareous rock formations. They (and similar examples elsewhere) may be distinguished as “rich fen,” though there is often a general understanding that a “fen” will be relatively eutrophic (nutrient rich). A classic plant of rich fen is saw-sedge (or simply “sedge”) (*Cladium mariscus*), which may be a key species in past or present management (see below). The definition of “fen” however often also covers sites with much lower mineral input and corresponding higher acidity; such areas may be described as “poor fen” and are commonly characterized by extensive development of *Sphagnum* moss carpets.

Fen may be defined by a pH generally above 6.0 and with relatively high levels of calcium and bicarbonate ions. The vegetation of such mires tends to be rich in herbs and “brown mosses” such as *Drepanocladus*, *Campylium* and *Scorpidium*, and *Cratoneuron*.

By contrast, *bog* is defined by a pH generally below 5.0, with low levels of calcium ions, and with chloride and sulfate ions as the main anions. Vegetation includes members of the heather family (*Calluna*, *Erica*, etc.), cotton grasses (*Eriophorum*), and other calcifuge (“calcium-avoiding”) members of the sedge family, and often an abundance of *Sphagnum* mosses.

On this definition, many examples of so-called poor fen or acid fen are better considered as “bog,” and this gives a more satisfactory treatment of phases and microtopography in complex acid mire systems.

Plants

Herbaceous fen (including open reed and sedge fens)

The open fens are usually dominated by tall reedlike grasses, such as common reed (*Phragmites australis*), small reeds (*Calamagrostis* species) or purple moor grass (*Molinia caerulea*), or by tall sedges such as *Carex acutiformis* or *C. disticha*, or by saw-sedge (*Cladium mariscus*), or locally by the blunt-flowered rush (*Juncus subnodulosus*). A variety of other tall herbs such as meadowsweet (*Filipendula ulmaria*) may be present, perhaps along with declining rarities such as the marsh pea (*Lathyrus palustris*). Below the field layer is likely to be a layer of mosses, including *Campylium* and *Cratoneuron* species. This may be a transitional phase or may be maintained by appropriate management.

Traditional management of many of the East Anglian fens has been the cutting of “sedge” (*Cladium*), primarily for thatch. Sedge is more flexible and durable than reed and was used for ridging reed-thatched roofs or, less often, for thatching entire roofs. It also had uses as kindling material and as a tough litter for floor coverings. Large areas were maintained for this purpose, and the survival of undrained fen fragments no doubt has been due to the value of sedge as a cop. However, there is

now much less demand and former sedge fens have in many cases been colonized by bushes to form *carr*. This has meant the local disappearance of many plants requiring these open conditions and is implicated in the extensive loss of invertebrates such as the swallowtail butterfly.

While there is still a small commercial demand, cutting sedge is now largely a conservation exercise. Management aims at, e.g., Wicken Fen are not only to maintain sedge fens but also to reclaim areas from *carr* and extend the open communities.

The areas dominated by grasses such as *Calamagrostis* species or *Molinia* were traditionally cut as “litter” for animal bedding. Like the sedge fens they tend to be herb-rich, and continued cutting on an annual or biennial cycle is required to maintain floristic diversity.

As noted above, poor fens (if considered “fens” at all) are likely to have a moss layer including or dominated by *Sphagnum* species. Purple moor grass (*Molinia caerulea*), bottle sedge (*Carex rostrata*), and the smaller sedges, such as *C. echinata* and *C. nigra*, may predominate among the vascular plants.

Carr (wooded fen)

Succession to carr (wet scrub and swampy woodland) is usually to be expected except where active management maintains the open areas. Lowered water tables caused by drainage within or adjacent to the fen complex may accentuate this, and since most surviving fens are surrounded by farmland, this may be a substantial management problem.

Bushes and trees forming carr must be capable of growing in waterlogged conditions with little oxygen supply to the roots. Willows and sallows (*Salix* species) may predominate, including gray willow (*S. cinerea* subsp. *Cinerea*), which often dominates East Anglian fens and occurs more locally north to central Scotland.

Two buckthorn species, the common or purging buckthorn (*Rhamnus cathartica*) and the alder buckthorn (*Frangula alnus*) are also locally abundant carr species in some of the East Anglian fens. Common buckthorn is not confined to fen carrs; it can be a component of scrub on dry chalk slopes. Alder buckthorn is more restricted to damper habitats.

At Wicken, both were abundant in the first part of the twentieth century and *Rhamnus* still is often being the dominant carr species. *Frangula*, however, suffered a decline through apparent fungal attack in the 1930s and has suffered other misfortunes since. It is currently, however, a typical pioneer species in young carr and appears to be recovering its former status.

Alder (*Alnus glutinosa*) is a larger tree that may come to dominate richer fens in some localities. It is notable as possessing rood nodules containing a symbiotic nitrogen-fixing actinomycete. Nitrogen may otherwise be deficient during development of fen woodland.

In poor fen, the shrub bog myrtle or sweet gale (*Myrica gale*) is no doubt even more important as another species that effects nitrogen enrichment via symbiosis.

On poorer sites, downy birch (*Betula pubescens*) is likely to become the dominant tree species, sometimes forming more or less pure woodland on the thicker peats.

History

In Anglo-Saxon and medieval times, the precious areas of dry land rising above the fen attracted the attention of religious communities. In truly grand style, they founded great cathedrals and monasteries, dominating the skyline and life of the surrounding Fens.

Ely: The ancient city of Ely occupies the largest island in the Fens. In the seventh century, St. Etheldreda founded a religious community on its hill top site. Rich in folk history, Ely was the stronghold of Hereward the Wake, who used the island to stage the final Anglo-Saxon resistance against the Norman invasion.

The main development of the city originates from the late eleventh Century when construction of the cathedral commenced. Both the cathedral and the surrounding Fens have played a major role in the history of Ely through the centuries.

Today, Ely is characterized by its pattern of narrow streets and monastic buildings, gathered around the spectacular cathedral. Visitors can explore the ancient buildings and medieval gateways, stroll along the riverside, or simply enjoy the peaceful relaxed charm of this historic city. In addition to the cathedral, there is Oliver Cromwell's house or the Ely museum for a fascinating insight into the history of the city and surrounding Fens.

Elsewhere in the Fens, the abbeys at Ramsey, Thorney, and Chatteris along with Spalding Priory were influential in the development of these market towns. Ten miles south of Spalding, the small town of Crowland is dominated by the remains of its medieval abbey. Still functioning as the parish church, and featuring an interpretative exhibition, the original abbey was founded in 716 in memory to St. Guthlac. Rebuilt between 1,114 and the fifteenth century, it was on a massive scale, dominating the surrounding Fens. Another landmark in Crowland is the unique medieval triangular bridge in the center of town.

Historic wash ports

Since medieval times the historic Fen towns clustered around the Wash have developed as important ports, enjoying a busy trade with the Low Countries and the Hanseatic League of German and Baltic maritime cities. Along with Boston and King's Lynn, the towns of Wisbech and Spalding, now several miles inland, once occupied positions on the medieval coastline of the Wash. Through drainage and reclamation, the Wash coastline is very different today. However, Wisbech, now 12 miles inland, is still an active port.

Boston: Situated on the banks of the River Witham, Boston has long traditions as a port and boasts a wealth

of buildings and architecture reflecting its great trading role. The skyline is dominated by St. Botolph's Church, England's largest parish church, rising 272 ft above the River Witham. Another imposing landmark is the Maud Foster Windmill, England's tallest working windmill.

The Guildhall Museum, dating back to 1,450, depicts the town's maritime history and features a free interactive computer simulation of what life was like around 1,536. The museum also includes the cells and courtroom where the Pilgrim Fathers were tried and imprisoned. Nearby in Spain Lane, Blackfriars Arts Centre is a lively venue housed in a thirteenth century Dominican friary.

King's Lynn: Over 900 years of maritime and trading history are preserved in the historic core of King's Lynn. Still a busy port and thriving commercial center, the town's medieval churches and guildhalls, secret courtyards, and hidden alleys leading down to the river combine with the lively atmosphere of two busy marketplaces.

Market towns

Throughout the Fens you can enjoy the traditional atmosphere and friendly slow pace of historic market towns, with a lifestyle much cherished in today's fast-paced world.

The town of March, originally a small island community, developed as a Tudor Port and later as a railway town in the nineteenth century. With the Old River Nene flowing through its center, it has been described as "The Thameside town in miniature," with many attractive cottages and buildings alongside the river. The fascinating history of the town is told in the March Museum.

Similarly, the towns of Chatteris, Littleport, and Whittlesey grew from small island communities. Whittlesey is characterized by the seventeenth century Butter Cross in the center of the marketplace. The town is an interesting maze of streets with well-preserved architecture spanning several centuries.

Littleport near Ely is famous as the scene of the Littleport Riots of the nineteenth century.

Chatteris is a typical Fenland market town popular with anglers and bird watchers attracted to the surrounding Fens.

To the south of King's Lynn, the attractive town of Downham Market occupies a site on the edge of the Fens. Characterized by its unusual clock tower in the marketplace, it is an excellent base for exploring Fen villages, such as Upwell, Outwell, and Stow Bardolph.

The story of the Fens

The history of the Fens is a fascinating story of a landscape and its people, where man and nature have interacted to create the Fens environment of today. It is a story of an amazing transition from the wetland wilderness of old to the people-made landscape of today. This spans the centuries from Bronze Age, Roman, and Anglo-Saxon times, when habitation was limited to isolated islands and a wide silt ridge which formed around the Wash. Between

Domesday and the thirteenth century, a gradual reclamation of land took place by building banks as flood protection from the surrounding uplands.

The Dark Ages saw a halt to reclamation; however, by the early seventeenth century, with economic recovery, the attention of speculators turned to draining the peat fens in the south and remaining undrained silt fens further north. Under the guidance of the fourth Earl of Bedford, the speculators or adventurers started work on the systematic draining of the Fens. Experienced civil engineers were commissioned, such as the Dutch civil engineer Cornelius Vermuyden, who undertook the greatest scheme, constructing the Old and New Bedford Rivers between Earith and Denver.

Local opposition was considerable as the systematic drainage of the land threatened the traditional fishing and wildfowling rights of Fen dwellers. Their fierce resistance and destruction of the drainage work earned them the name "Fen Tigers."

Drainage schemes continued, but unexpectedly, the land began to shrink at an alarming rate as the soil dried out. As the level of the land dropped, water could no longer drain into the rivers which were by now higher than the fields. Wind pumps were introduced to pump water off the land and into the rivers, but their reliance on adequate wind and continued shrinkage of the land saw the task become increasingly difficult. It was not until steam power was introduced in the 1820s that the Fens were effectively drained.

At one time the Fens landscape was once dominated by up to 700 windmills, built in timber or brick to drain the land or mill the corn. Many have since disappeared, yet some still survive, towering over the Fens. These include Denver Mill near Downham Market, the Great Mill Haddenham, Downfield, Stevens, Wicken and Swaffham windmills south of Ely, Sibsey Trader Mill north of Boston, and Maud Foster Windmill in the town of Boston at seven stories high, the tallest working windmill in Britain.

Today there is a sophisticated network of drains, embankments, and pumps to protect the land from the ever-present threat of rain and tide.

Produce

Generations of Fen people have maintained a close kinship with the land. History, nature, and the ingenuity of man have provided a landscape unrivaled for its rich fertile soils and abundant variety of crops.

From the rich dark peaty soils in the south and west to the fertile silt of the north, wherever you go in the Fens, you will find a wide variety of different flowers, fruit, and vegetable crops being grown. Different crops are grown to suit local soils and conditions – apple orchards, soft fruit, and strawberries around Wisbech; cabbages, cauliflower, and Brussels sprouts around Boston; flower bulbs around Spalding; carrots and celery in the peat soils around Ely and Chatteris.

Throughout the seasons, the ever-changing landscape offers wonderful floral displays. Yellow carpets of daffodils in spring, vivid summer displays of roses in bloom, and spectacular flower festivals demonstrate the importance of flower growing in the Fens.

The Fens are the center of Britain's bulb and seed industry, a rich heritage proudly displayed through festivals, show gardens, and flower displays.

Wetlands: Classification, Distribution, Function

FINNISH LAKES

Esko Kuusisto

Finnish Environment Institute, Fresh Water Centre,
 Helsinki, Finland

Description

From the estimated number of 10–15 million lakes in the world, well-over half are located in the northern boreal zone. In Finland, a detailed lake inventory was made in the 1980s with the following results (Kuusisto and Raatikainen, 1988):

Area (km ²)	Number of lakes
>100	47
10–100	279
1–10	2,283
0.1–1.0	13,094
0.01–0.1	40,309
0.0005–0.01	131,876

This brought the total number to 187,888, over three times higher than the previous estimate published in the 1950s. The increase was simply due to the myriad of ponds smaller than 1 ha, their number being as high as 131,876. The lower size limit was set to 0.05 ha.

In practice, these figures can naturally not be accurate to the last digit. The sizes of water bodies vary according to hydrological conditions, causing them to cross class boundaries. The shores of shallow lakes are not well defined on the basic maps 1:20,000, which were used in the work. All map sheets, 3,610 of them, were checked twice; the work took over two person-years.

Lake routes are a typical feature particularly in the Finnish Lake District. This provokes the question: when does one lake end and the next one begin? And when the river waterway settles itself, when does still water have enough plump to be a lake? These matters have a moderately good solution in the following specifications of lake definition:

- The water surface is the same at different parts of the water area, aside from temporary wind- or ice-caused exceptions.
- The outflow–volume relationship is so small that a great majority of sedimentary materials drop to the bottom.

In practical counting work, these specifications were not of great use: only in rare cases the counter was able to compare the water surface level readings marked on a map. Solutions had to be worked out by “this is how I feel” method.

Still there was a problem with the numerous small ponds on aapa mires. It was decided that they will be counted as only one water body. In such swarms, the water surface is however all the same, because all bonds are hydraulically in contact with each other.

Five river basins in Finland have slightly over 20,000 water bodies. Among those are the two largest basins, Vuoksi (52,600 km²) and Kemijoki (49,500 km²). They have lake densities of 43 and 44/100 km². The other three are located in northern Lapland with considerably higher lake densities: Paatsjoki (138/100 km²), Tenojoki (470), and Näätämöjoki (920). The topography in that region is small-scale, and in every depression there is water. One single basic map, having an area of 100 km², has as many as 1,960 water bodies, almost 90% of them being smaller than 1 ha. Alongside the Lake District, Finland thus also has the Pond District.

Not all of the lakes are fully in Finland. There are 182 shared with Russia, 120 with Norway, and 13 with Sweden. The largest lake shared with Sweden is Kilpisjärvi (37 km²), but a much larger one is shared with Russia (Kitee’s Pyhäjärvi, 200 km²).

The depth charting of Finland’s lakes began in 1856 from Tampere’s Pyhäjärvi. The work was soon continued in several large lakes in order to improve the safety of inland water transportation. The focus was first on the numerous straits and narrows.

At the end of 2009, over 89% or 29,600 km² of the Finnish total lake area is mapped. Unsounded areas are decreasing by about 300 km² a year. The deepest lake is Päijänne, 95 m, followed by Inari (92 m) and Suvasvesi (90 m). Lake Suuri Jukajärvi in southeastern Finland has the highest mean depth, 23 m (Kuusisto and Hakala, 2007).

The surface of about 3,000 lakes has been lowered in Finland, most of them in the nineteenth century. The main reason was a demand for agricultural land. Quite many of those lakes dried completely, but a number of them became shallow and eutrophic. Among those are

nowadays some of the most important bird sanctuaries of the country.

Most of Finland’s large lakes were formed during the Ice Age and shaped by the land uplift. Päijänne and some other major lakes were born from faults in the bedrock formed hundreds of millions of years ago. Around ten lakes, the largest ones being Lappajärvi and Paasivesi, have been created by meteorite impacts.

Water quality is good or excellent in over 80% of Finland’s lake area, although many shallow lakes require attention. Almost 1,000 rehabilitation projects have been completed in recent decades. The most common methods are removal of aquatic plants, improvement of food chains, and oxygenation. Another factor in improving

Finnish Lakes, Figure 1 The areal distribution of lakes in Finland. There are only a few major lakes in the coastal areas. In the Lake District, water covers over one fifth of the area.

10	Höytiäinen	293	57	160	17

water quality has been significant investments in the removal of nutrients from urban and industrial wastewaters.

The Water Framework Directive of the EU came into effect in 2000, with the aim of achieving a high ecological status for surface waters by 2015. Collaboration is closer between authorities and local residents in Finland than in most other countries. Due to their love of local lakes and the scarcity of public funding, lakeshore residents have been inspired to start up lake protection groups and to work together in maintaining their lakes.

Many of Finland's towns are located on a lakeshore. A good example is Tampere, where the power of rapids attracted several large industrial plants in the nineteenth century. Most heavy industry has now left the area, and the old factory buildings have been put to cultural use.

Canals and locks have been built to facilitate inland water traffic in the Lake District. The Vuoksi, Kymijoki, and Kokemäenjoki river basins contain a total of almost 40 locks and 30 open canals. The most extensive network of boating routes is in the Vuoksi basin, including nearly 600 km of 4.2-m deepwater channels, some 1,000 km of 2.4-m channels, and several hundred kilometers of 1.8- and 2.1-m channels. This network is also connected to the Baltic via Saimaa canal, making this, the EU's largest lake navigation area, important to Eastern Finland's economy.

Long-term monitoring of lakes has been conducted in Finland. The freezing and thawing of Kallavesi and Näsijärvi have been recorded since the 1830s; the water level in Lake Saimaa has been recorded daily since 1847. On some lakes, surface water temperatures and ice thickness have been monitored for nearly a century (Korhonen, 2002, 2005).

Lakes have slow currents that are very important to their ecosystems. Today's technology can determine a lake's flow field in great detail from the surface to the bottom; this is a sector in which Finnish researchers are at the forefront.

A map of the areal distribution of lakes in Finland is shown in [Figure 1](#); [Table 1](#) gives some characteristics of ten largest lakes.

Definition

Phytoplankton – Free-living autotrophic and mixotrophic eukaryotic and prokaryotic cells.

Introduction

Lakes cover 10% of the area in Finland and the number of lakes with a surface area >100 km² is the highest in Europe. Similarly as in many other countries in Europe, also in Finland, major changes in nutrient loadings took place after the Second World War (Simola and Arvola, 2004). As a result, the ecological condition of many lakes deteriorated, and only since 1970s, the water quality of the lakes and rivers started slowly to improve due to wastewater treatment plants and thus a decline in sewage waters (Niemi et al., 2004). However, atmospheric deposition (especially nitrogen deposition) and loadings from agriculture have strongly increased since 1950s, and in many lakes, the load from agriculture has become the main source of nitrogen and phosphorus.

Besides eutrophication, in Finland, there are also regional differences in the background loading with more fertile soils on the coast of the Baltic Sea (Leka et al., 2008) than in areas further in North and East. In Northern and Eastern Finland, there is much less agriculture than in South, and landscape is even more dominated by forest and peatlands. Besides the bedrock and soil properties,

Finnish Lakes, Trends And Regional Differences of

land use, atmospheric deposition, and climate explain the wide variation in nitrogen and phosphorus concentrations in Finnish lakes (e.g., Lepistö et al., 2006; Sippola and Yli-Halla, 2004).

In unproductive lakes in the northern temperate region, phytoplankton can be nitrogen limited rather than phosphorus limited (Rekolainen et al., 2004; Bergström et al., 2005; Bergström and Jansson, 2006; Weyhenmeyer et al., 2007), which is in conflict with the generally accepted concept of phosphorus-limitation in temperate lakes (Vollenweider, 1968; Dillon and Rigler, 1974; Schindler, 1977). In Finland, Pietiläinen and Räike (1999) and Räike et al. (2003) have earlier suggested, however, that in large lakes, phosphorus would be the limiting nutrient for phytoplankton.

In this chapter, long-term trends and regional differences in phytoplankton in 19 large Finnish lakes are reviewed. The study lakes represent 38% of the total number of large lakes (>100 km²) in Finland and they distribute from the South (61°) to the North (69°). The used data sets cover the uppermost 0–2 m of the water column and the summer season, i.e., June, July, and August. Samples for water chemistry and chlorophyll *a* were collected since 1980 and for phytoplankton since 1982. For more detailed information on the material and methods as well as results, see Arvola et al. (2010).

Trends in phytoplankton

Phytoplankton biomasses declined since the early 1980s in 15% of the study lakes (Figure 1). For diatoms, the trend is less consistent, however, because the biomasses of

centric diatoms have decreased in almost 15% of the lakes while the biomasses of Pennales diatoms have increased in nearly one third of the lakes. The share of green algae in the total phytoplankton biomass has also increased in a similar way to that of the Pennales diatoms, while in chlorophyll *a* an increasing trend was found in three lakes of 19 and a decreasing trend in two lakes. At the same time, total phosphorus (TP) concentrations declined

significantly ($p < 0.1$) in >40% and total nitrogen (TN) in >25% of the lakes.

The mean summer chlorophyll *a* concentration of the lakes correlated strongly with TP while the relationships between chlorophyll *a* and nitrate-nitrogen were not significant but a weak positive trend was observed in June. It seemed that TP and chlorophyll *a* concentrations follow each other closely in the study lakes irrespective of their

Finnish Lakes, Trends And Regional Differences of Phytoplankton, Figure 2 The study lakes classified by the clustering technique according to the (a) major nutrients and chlorophyll *a* concentrations, and (b) mean biomass of the most abundant taxonomical groups of algae (including cyanobacteria). The numbers represent the following lakes: 1 = Vesijärvi, 2 = Yli-Kitka, 3 = Saimaa, 4 = Päijänne, 5 = Säskylän Pyhäjärvi, 6 = Pyhäjärven Pyhäjärvi, 7 = Karjalan Pyhäjärvi, 8 = Pielinen, 9 = Näsijärvi, 10 = Oulujärvi, 11 = Längelmävesi, 12 = Lentua, 13 = Lappajärvi, 14 = Konnevesi, 15 = Koitere, 16 = Kemijärvi, 17 = Kallavesi, 18 = Inari.

geographical location or trophic. The regression between the biomass of algal groups and TP was highest for chlorophytes and Pennales diatoms, and lower for chrysophytes and centric diatoms (Table 1).

When the same procedure was used to cluster the lakes according to the biomasses of the major taxonomical groups of algae, cyanobacteria, chrysophytes, green algae, and diatoms, three major clusters were identified (Figure 2). The four lakes in group A consisted of relatively high productive lakes. The lakes in group (B) were more diverse but at least two of them have experienced re-oligotrophication. The lakes in the third group (C) consist of oligotrophic lakes, and most were situated in the East or the North. All the lakes in group A had total biomasses and cyanobacterial biomasses that were higher than in the lakes in the other groups while the share of chrysophytes was lower. A characteristic feature for the lakes in group C was the increased importance of chrysophytes which contributed, on average, 22–36% of the phytoplankton biomass.

Regional differences

In geographic terms, the nutrient concentrations decreased toward to the East and North and there was an associated decrease in the chlorophyll *a* values toward to the East. Toward the North, the decreasing trend of chlorophyll *a* was not significant, however.

When the lakes were subjected to a hierarchical cluster analysis according to their nitrogen and phosphorus concentrations, five lake groups were formed (Figure 2a). The first group consisted of the eutrophic lakes with highest nutrient concentrations. The second group consisted of meso-eutrophic lakes, while the third group included lakes situated in the southern part of the country and with a oligo-mesotrophic nutrient status. The fourth group consisted of lakes situating in the eastern and northern part of the country and with oligo-mesotrophic status. The “residual” group included only one lake in the far North with an ultra-oligotrophic status.

Summary

The chemical data clearly suggest that a systematic change in major nutrient (N, P) concentrations and the N:P ratio has taken place in Finnish large lakes, although in most lakes the rate of change has been relatively small as has also been shown by Pietiläinen and Räsänen (2001) and Niemi et al. (2004). Respectively, lower loading has resulted in lower phytoplankton biomasses in many lakes also during recent years in comparison to the early 1980s. Interestingly, the number of lakes where the biomasses have declined is lower than the number of lakes where the TP concentrations have declined which may indicate a delayed response in phytoplankton relative to the decreased nutrient loadings and concentrations (see Willén, 2001). Internal loading might be another reason for the delay. The long-term changes observed in the biomass of phytoplankton were

generally matched by the changes in the composition of the phytoplankton. The species and groups known to prefer oligotrophic conditions, such as the chrysophytes, were more abundant in oligotrophic lakes and those favoring eutrophic conditions, such as the cyanobacteria and particularly the order Chlorococcales green algae, were less abundant. These observations are in line with the results from other Nordic lakes (see Willén, 2001; Ptacnik et al., 2009).

Different algal species and taxonomical groups have their own physiological and ecological strategies and constraints (Reynolds, 1984), including nutrient preferences, which was clearly seen in the phytoplankton communities of lakes located in different regions. For example, the share of centric diatoms (Centrales) clearly increased from Southern to Northern Finland, i.e., from the higher nutrient concentrations to lower ones. Similarly, the share of pennate (Pennales) diatoms decreased from the West to the East, that is, from the higher nutrient concentrations to the lower ones (see Ptacnik et al., 2009). Thus, the proportion of two diatom groups with contrasting preferences to nutrient conditions showed quite a different regional distribution. Similarly, the share of chrysophytes has increased and the changes in the spatial distribution follow that of the Pennales diatoms. In contrast, cyanobacteria and particularly Chroococcales species were more abundant in lakes with higher nutrient concentrations. Major changes in the phytoplankton were observed in one third of the studied lakes. More importantly, such a clear geographical gradient in the phytoplankton from Southern to Northern and from Western to Eastern Finland has not previously been reported in the large Finnish lakes. These differences in the composition of the phytoplankton community clearly reflected the underlying differences in the major nutrients. This implies that nutrients seem to be the key driver for phytoplankton growth regardless of the lake's geographical location.

Several factors could account for the regional differences in the trophic status and phytoplankton of the large lakes in Finland. Among the most important are the soil type and its nutrient content, which in turn reflect the bedrock and the post-glacial history of the area. The recent land use in the catchment is also an important factor although this cannot be wholly separated from the soil type and bedrock. In general, the results reported from the Swedish large lakes by Willén (2001) are very similar with the limitation of phosphorus for phytoplankton and long-term reductions in the concentration of phosphorus and the biomass of phytoplankton.

In conclusion, long-term declines in TP and TN concentrations were found in nearly half of the lakes which also coincided with major changes in phytoplankton biomass. A clear regional gradient from Southern to Northern and from Western to Eastern Finland was observed in phytoplankton and nutrients. The role of phosphorus as the limiting nutrient was evident while the N:P ratio had a low value in predicting the occurrence of cyanobacteria.

Definition

Floodplain – flat land or low land bordering rivers that are subject to periodic flooding.

Alluvial – soils occur along watercourses occupying nearly all level areas subject to periodic flooding.

Introduction

A floodplain is a plain land formed along the course of a river by the deposition of sediment, typically dropped by a river during periodic floods. Any obstruction across a river's course, such as a band of hard rock, may form a floodplain behind it, and indeed anything that checks a river's course and causes it to drop its load will tend to form a floodplain. Floodplains are formed in two ways: by erosion and by aggradation. An erosional floodplain is created as a stream cuts deeper into its channel and laterally into its banks. Material is added to the floodplain during floods, a process called overbank deposition. The material that underlies floodplains is a mixture of thick layers of sand and thin layers of mud. Floodplains are neither static nor stable. Composed of unconsolidated sediments, they are rapidly eroded during floods and high flows of water, or they may be the site on which new layers of mud, sand, and silt are deposited. As such, the river may change its course and shift from one side of the floodplain to the other.

Floodplains can be looked at from several different perspectives. As a topographic category, it is quite flat and lies adjacent to a stream; geomorphologically, it is a land-form composed primarily of unconsolidated depositional material derived from sediments being transported by the related stream; hydrologically, it is best defined as a land-form subject to periodic flooding by a parent stream. A combination of these [characteristics] “Perhaps these perspectives may fulfill the essential criteria for defining the floodplain” (Schmudde, 1968). The characteristics and functions of a floodplain are intimately linked to the river that flows upon it. When unregulated, floodplains are highly dynamic like most fluvial landforms, and frequently inundated by overbank floods.

During high water events, some of the water is absorbed by the floodplain, helping to keep the river from overflowing. The absorbed water can then be returned to the stream during times of low water. If a high water event is large enough, water will overflow the channel of the river and flow onto and spread over the floodplain, which slows the flow of the water. Reduced water flow can help prevent severe erosion and flooding downstream. Floodplains are also home to many types of plants and animals and may also have forests and wetlands on or adjacent to them. These river edges provide habitat for insects, birds, reptiles, amphibians, and mammals. The vegetation also helps filter contaminants out of the water flowing into the river. Additionally, vegetated floodplains provide shade for the adjacent rivers and streams, increasing dissolved oxygen levels and consequently improving habitat for aquatic plants and animals.

Floodplains are most commonly found near the mouth of a large river, such as the Rhine, the Nile, or the Mississippi, where there are occasional floods and the river usually carries a large amount of sediment. Floodplains contain such features as levees (river embankments built by deposition as the river floods), backswamps, delta plains, and oxbow lakes. Rivers with extensive floodplains are the Nile, Ganges, Danube, and Po. People have been lured to floodplains since ancient times, first by the rich alluvial soil, later by the need for access to water supplies, recreation, etc.

The categorization of different varieties of wetlands into marshes, swamps, peat lands, and floodplain wetlands was first done by Maltby (1991). Investigations on various aspects of floodplain wetlands (Hoffmann, 1998) were mostly conducted during the past three decades only after the Ramsar Convention. However, knowledge about the characteristics and functioning of floodplain wetlands is important in order to restore and maintain them. Despite their importance, floodplain wetlands have been one of the least valued and most abused of world's natural resources today. These important wetland ecosystems are being exploited by the mankind for various activities, leading to degradation. Changes in climate and hydrology, blockage of floodplain flows, disposal of storm water, excessive grazing by native animals, agriculture and aquaculture practices, and recreational developments are some of the important causes of degradation.

Functions and values

Floodplain wetlands, in their natural state, have been cited to be of particular value since they have a high biodiversity, provide critical habitats for many plants and animals, and are an important, natural element in the maintenance of water quality (Mitsch and Gosselink, 1986; Whiting and Pomeroy, 1997; Takatert et al., 1999). Floodplain wetlands are essential to the maintenance of the hydrological, physical, and ecological health of our life support system – the riverine environment. They provide economic, social, and cultural benefits through their ability to enhance water quality, conserve flora and fauna, and mitigate floods, fishing and agricultural-related activities. The floodplain wetlands provide many recreational, educational, and scientific opportunities and add diversity to our landscape.

Floodplain wetlands of India

Floodplains and their associated wetlands are utilized by human beings throughout the world. Nowhere, this is truer than in Asia owing to high population density, thereby creating huge pressures on all forms of natural resources including the floodplain wetlands. India is naturally endowed with 0.2 million hectares of floodplain/oxbow lakes (*beels*) of which the state of Assam has the maximum number and the largest water spread area is mainly associated with the Brahmaputra and Barak river systems (Sugunan and Bhattacharya, 2000; Sugunan et al., 2000). The floodplain wetlands in India are an important resource for livelihood, both for rural and urban communities. These wetlands are widely distributed throughout the Eastern and Northeastern part of India under river Ganga and the Brahmaputra basins. Floodplain wetlands form the prime fishery resource in the states of Uttar Pradesh, Bihar, West Bengal, Assam, Manipur, Tripura, Arunachal Pradesh, and Meghalaya, where they are commonly known as beel, maun, tal, jheel, pat boar, chaur, etc.

Kaziranga National Park

Kaziranga National Park, the home of the great Indian one-horned Rhinoceros, is situated on the banks of Brahmaputra river (Figure 1). The terrain of the park comprises the floodplains of the Brahmaputra river, which is in general flat. The park area is bounded by latitude 26° 30'N and 26° 45'N and longitude 93° 05'E and 93° 40'E. It is one of the significant natural habitats for in situ conservation of biological biodiversity of universal value and included in the UNESCO World Heritage Site List in the year 1985. The Kaziranga National Park area consists of 429.93 km² with an additional area of 429.40 km² and situated in the two districts of Assam, namely, Golaghat and Nagaon.

Since Kaziranga area forms a part of the vast alluvial plains of the Brahmaputra river and its tributaries, the deposition of silt brought by these rivers during the rainy season each year gives rise to land masses getting stabilized over a period of time. The floodplain area of the

Floodplain Wetlands: Focusing on India, Figure 1 Satellite imagery of Kaziranga National Park, Assam, India, showing numerous floodplain wetlands and Brahmaputra river.

national park consists of a number of meander scars, wetlands, curvilinear streams, etc. A huge number of wild animals including one-horned rhinoceros (two-third of the world's great one-horned rhinoceros population) seek shelter in this park and the floodplain wetlands are the most favored habitat for one-horned rhinoceros. About 5.58% of the total area of the park is covered under floodplain wetlands locally known as "beels" during dry months. These wetlands ecosystems are highly productive and most important and significant natural habitats for in situ conservation of biological diversity, including those containing threatened species of outstanding universal value from the point of view of science or conservation.

Although significant progress has been made in the conservation of the national park and its inhabitants, Kaziranga continues to face both natural and man-made challenges. Natural challenges include the flooding of vast areas of the forest during the long monsoons, which takes its toll on the animal population in particular the rhinoceros. The forest department has tried to address this in small measures by constructing several elevated land banks where animals can take refuge during floods. Conservation measures have also been implemented to arrest deforestation, soil erosion, etc., which deplete the area of its green cover. Recognizing the importance of its World Heritage Site status and global significance of this asset, the government has been dedicating increasing resources and working with international bodies to ensure that the Kaziranga National Park retains its distinctiveness as a vital global biodiversity hotspot and as a important floodplain wetland of national importance.

Summary

In the future, climate change may severely alter flood patterns over large regional scales. Consequently,

besides other anthropogenic factors, climate change represents a potential threat to river and associated floodplain ecosystems. The sustainable management of floodplain wetlands is an important issue and the policy makers should aim at research, planning, management, and education for adopting appropriate conservation measures.

FORTH AND CLYDE AND UNION SHIP CANALS, UK

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Definition

These busy canals in Central Scotland cross each other, the levels differing by 34 m.

The canals had been originally linked by 11 locks over a 1.5-km distance but these were dismantled in 1933. It was therefore considered to again link the two canals and a unique lift was devised, now known as the Falkirk Wheel, the world's first canal rotating boat-lift.

The Falkirk Wheel is located close to the Roman Fort at Rough Castle and to the best preserved section of the 55-km-long Antonine's Wall. Two boat "gondolas" on the end of curving arms balance each other so that the half rotation to change canal levels takes about 15 min with the

minimum of energy. The gondolas can take eight or more boats.

At the beginning of each cycle, each gondola will be at the level of one of the canals while boats enter and leave. The motors then turn the precisely balanced wheels through 180° and when each has come to rest the boats will be let out at the other canal level.

The process is aided by the use of Archimedes Principle whereby boats displace their own weight of water so that the tanks being full to the brim each boat that enters pushes out water that weighs exactly the same as the boat. The tanks therefore remain completely balanced.

The canals are fed by canal lochs, the largest being Cobbinshaw Loch south of Edinburgh

The Falkirk Wheel was opened by Her Majesty Queen Elizabeth II in 2002 and the Forth and Clyde Canal was considered, by the Institution of Civil Engineers and the American Society of Civil Engineers, an International Historic Civil Engineering Landmark, and a plaque in recognition of this accolade was erected by both institutions at the Falkirk Wheel in 2000.

G

GENEVA LAKE

Ulrich Lemmin
ENAC, Ecole Polytechnique Fédérale Lausanne (EPFL),
Lausanne, Switzerland

Introduction

Lake Geneva (local name: Lac Léman; Lacus Lemanus in Roman times) is a large, crescent shaped, deep lake of glacial origin, located between Switzerland and France ([Figure 1](#)). It is the largest lake in Western Europe, and it consists of a deep eastern main basin and a small, shallow, narrow western basin, locally called Grand Lac (Great Lake) and Petit Lac (Small Lake), respectively. Physical characteristics of the lake are summarized in [Table 1](#).

Lake Geneva is surrounded by the Jura Mountains to the northwest and by the Alps to the south. Most of the northern and western parts of the basin lie on a flat plateau. Steep alpine slopes, which rise to more than 1,000 m above the mean water level within 2 km of the shoreline, bound the lake basin to the east and southeast ([Figure 1](#)).

The main basin is characterized by a large bottom plateau in the center, limited by the 300-m isobath ([Figure 1](#)). A N-S cross section of the lake basin changes gradually from a U shape with steeply sloping sides and a bed material mainly composed of large boulders in the east, to a V shape with gentle slopes, mainly composed of fine sands, in the west.

Most of the catchment area is located in the Alps to the east and south of the lake basin with elevations up to 4,000 m. The ratio of the catchment area to the lake surface is 12.7, and snowmelt in the spring is an important process of water renewal. The main inflow to the lake is the river Rhone, which enters the basin from the east. The rivers Aubonne and Venoge, flowing down from the Jura Mountains in the north, and the alpine river Dranse in the south are secondary contributors to the hydraulic load. The only outflow from the lake is the Rhone river in Geneva at the western end of the lake, where the water level of the lake is controlled by a weir. In the water mass balance, river inflow and outflow clearly dominate over precipitation and evaporation, making Lake Geneva a fluvial lake with a theoretical residence time of about 12 years.

Climate, windfield, and thermodynamic state

Lake Geneva is situated in a temperate climate zone that is influenced by the Atlantic Ocean and the Mediterranean Sea. However, cold, dry air originating in the Siberian plains can make intrusions, mainly during the winter months. Monthly mean air temperature values range approximately from a minimum of 1°C in the winter to a maximum of 20°C in the summer. Annual mean air temperatures vary between 7°C and 12°C, with a long-term mean of 10.6°C. This has slightly increased over the past 30 years.

Geneva Lake, Figure 1 Satellite image showing Lake Geneva and the surrounding area. Main depth contours are shown. Arrows indicate mean wind directions.

Geneva Lake, Table 1 Physical characteristics of Lake Geneva

Mean geographical coordinates	46°27'N 6°32'E
Elevation of mean water level	372 m
Maximum depth	309 m
Mean depth	152.7 m
Length along axis	72.3 km
Max. width	13.8 km
Length of shoreline	200 km
Surface Area Total	582 km ²
Great Lake (86%)	500 km ²
Small Lake (14%)	82 km ²
Volume Total	89 km ³
Great Lake (96%)	86 km ³
Small Lake (4%)	3 km ³
Drainage basin	6'380 km ²
Mean inflow	182 m ³ s ⁻¹
Mean outflow	250 m ³ s ⁻¹

The windfield over the lake is strongly influenced by the local topography and is dominated by NE and SW winds, known by their local names as “Bise” and “Vent,” respectively (Figure 1). “Bise” winds are typically cold and dry, whereas “Vent” winds are warm and humid. Mean wind speeds are generally low; wind speeds greater than 5 ms⁻¹ are rare. They typically occur as short events and generate most of the water circulation in the lake.

Lake Geneva is a warm monomictic lake. It is strongly stratified throughout the summer season, with a thermocline developing at a depth of about 20 m. In the deep hypolimnion which has a thickness of more than 200 m, water temperatures change little as summer progresses. Cooler fall and winter air temperatures cause the thermocline to deepen and to gradually erode. Depending on the meteorological conditions in the winter, the lake may destratify at the end of the cooling period in late February, giving rise to homothermal conditions in the water column and cooling down to the bottom. However, this phenomenon is an exception. Typically, a weak stratification remains for several years, resulting in a saw-tooth pattern of deep water temperatures (Figure 2). This stratification pattern of the bottom water layers has a direct effect on the oxygen content of the hypolimnion (Figure 3) and thus on the biochemical cycle. A continuous increase of the mean annual air temperatures over the recent decades has caused annual mean temperatures to rise in the top (Figure 4) and bottom layers of the lake (Figure 2).

Due to the event structure of wind forcing, mean current circulation patterns in the lake are weakly developed. Currents in the upper-layer near-shore zone are the strongest, ranging from 5 to 20 cm⁻¹ for several days after wind events. On the central plateau at 309-m depth, current speeds vary from 3 to 7 cm⁻¹. Kelvin waves and Poincaré waves are strong contributors to the current field in the stratified lake.

GIPPSLAND LAKES

Brian V. Timms

Department of Science and Information Technology,
 School of Environmental and Life Sciences, University of
 Newcastle, Callaghan, NSW, Australia

Introduction

The Gippsland Lakes of eastern Victoria, Australia, centered on 38°00' S, 147°30' E, comprise many interconnected lakes with a combined area of ca 400 km² (Bird, 1978). They are coastal lagoons enclosed from the sea by depositional barriers, but in the Australian context, they are big and permanent enough to be regarded as lakes. They owe their presence and form to a combination of geological, hydrological, and marine processes, and within the lagoons, wind-generated waves and currents, tidal and river currents, and ecological conditions have contributed to erosion and sedimentation.

The principal lakes from west to east are Lake Wellington (138 km², <4 m deep), Lake Victoria (110 km², up to 10 m deep), and Lake King (92 km², mainly <6 m deep but up to 15 m in a scour hole). Lakes Wellington and Victoria are connected by McLennan Strait, 12 km long and up to 11 m deep. The Latrobe and Avon Rivers empty into Lake Wellington, and the Mitchell and Tambo Rivers into Lake King. There are also three long, narrow, and shallow lakes adjacent to the coast from west to east: Lake Reeves, Bunga

Arm, and Cunninghame Arm. The latter has an artificial opening to the sea, dating from 1889 which replaced a natural opening at the eastern end of the Arm that used to close periodically. The combined lakes have a catchment of 20,000 km² and lie in a mild, moist maritime climate. Annual rainfall of near 770 mm lacks seasonally, but annual evaporation of near 1,000 mm is strongly seasonal, so there is a deficit in summer/autumn. Salinity varies from almost fresh at times in Lake Wellington to seawater salinities at the entrance, with much of the system in the range 5–20 mg/L. Salinities are higher in summer than in winter and have increased since the entrance was artificially opened to the sea. Before this, the lakes often flooded in winter/spring and were almost fresh for a short period.

Fluctuations in lake levels are complex. Spring tides at the entrance to the lakes are about a meter, but tidal movements are soon dampened within the lake system. The eastern end of Lake King experiences tidal movements of 10 cm, while they are imperceptible westward of Lake King. Changes in atmospheric pressure change levels by a few centimeters, while wind-generated seiches along the west–east axes of the lakes can cause 60 cm variations and river floods can increase heights by up to 2 m for a few weeks. Together, these factors cause irregular changes in water level around the lake, no more apparent than McLennan Strait where there are unpredictable sharp alterations in current flow.

The shaping of the coastal embayment in which the Gippsland Lakes lie began in Tertiary times. The eastern highlands to the north were uplifted in the late Tertiary, and during the Pleistocene, there was further tectonic deformation along the Latrobe syncline which runs east–west and under Lake Wellington. During the Pleistocene and into the Holocene, there were numerous marine transgressions and regressions due to eustatic sea-level changes. A small tidal range combined with an abundant supply of sediments promoted the building of offshore barriers by refracted ocean swell. The dominant swell arrives parallel to the coastline, but there is sufficient refracted swell from the southwest to promote longshore drifting to the east.

Three partly overlapping barrier formations have been built. Each consists of beach ridges and swales parallel to the present beach alignment of Ninety Mile Beach (Figure 1) and widened by progradation on the seaward side. Parabolic dunes cross the parallel dunes in places, creating chaotic relief and swamps within the trailing arms. The earliest set of dunes, the Prior Barrier, formed against the old cliffed coastline near the river mouths and at a time when the sea level was about 2 m higher than present. It consists mainly of quartzose sands but with a significant component of reworked river gravels. Presently, it can be recognized on the northeast shore of Lake Wellington, beyond the northern shore of Lake Victoria and as Raymond Island in Lake King. Much of this initial barrier has been reworked both during low sea-level phases and along the present shores of the lakes, particularly Lake Victoria.

The inner barrier was formed to the seaward soon after the deposition of the prior barrier, firstly by growth of

Gippsland Lakes, Figure 1 Map of the Gippsland Lakes, Victoria, Australia, showing places mentioned in the text.

a spit from the western end and eventually as a series of old beaches across the mouth of the large embayment. It enclosed a narrow intervening lagoon, now Lake Victoria, which flooded out each end to large lagoons, now Lakes Wellington and King, respectively, with irregular shorelines abutting the drowned coastline. A series of parallel dunes developed from the beaches, each by aggradation seaward, and when the sea level was about 2 m higher than present. These dunes consist almost entirely of silicious sands that were deposited in earlier times on the seafloor.

Then followed a major drop in sea level which lasted from at least 75,000–20,000 years before the present. The lagoons were drained and the rivers entering them flowed across the dry floors, combining to enter the sea off the eastern end of Lake Victoria and near Sperm Whale Head, a prominent part of the inner barrier. During this time, large parabolics formed, particularly in the inner barrier, including Sperm Whale Head. The center of these dunes was blown out well below the present sea level and, today, is marked by swampy infills and small lagoons.

With the sea level rise in the early Holocene, largely completed 6,000 years ago, an outer barrier quickly formed in front of the inner barrier, so that the ocean swell hardly reached it. Again, it grew from the southwest and was incomplete for some time in the Sperm Whale Head area. The barrier is best developed in the southwest with 13 closely spaced ridges and least developed in the east with only one ridge. There are recurvatures and old channels behind it, telling of stages in its growth. Also, it varies markedly in width in keeping with the joining of offshore islands and the recurvatures as the barrier grew. The outer barrier takes the same alignment across the larger embayment as the inner barrier and shallow

elongated lagoons (Lake Reeves, Bunga Arm) are trapped between them.

The lake shorelines have been modified by erosion and deposition, due largely to wind-driven wave and current action. Extensive deposition of riverine deposits and in situ organic materials has filled in the sheltered back waters and drowned valley arms, particularly in Lake Wellington, western Lake Victoria, and Lake King. These areas are still swampy, being at or near present lake levels, and are often inundated during flood inflows. Some (e.g., Tucker Lagoon) remain as open water, mainly to the south of Lake Wellington. Where lakes abutt sandy shorelines, sand is moved along the shore to form cusped headlands and spits. These occur in a regular pattern along the narrow Cunninghame Arm, where they are interpreted as initial stages of lake segmentation. This process is common in lakes with sandy shores in windy environments (Lees, 1989). The most obvious deposits, however, are the deltas of the main rivers. Most of these (Latrobe, Avon, and particularly the Tambo) open into exposed waters so that the deltas are cusped in form. However, the Mitchell delta has grown into protected waters of northwestern Lake King, so its sediments are not well dispersed and a finger delta has resulted. Its lower reaches are spectacular as it heads eastward across the lake under the influence of the prevailing westerly winds.

Some sedimentation is due to marine sands being washed into the lagoons. This has occurred mainly at the western end of the outer barrier where the sea rarely breaches the barrier and fans have developed partially across Lake Reeves. Also, there has been some redistribution of sands near the artificial entrance, though most of this is offshore in the form of a curved sand bar.

Though the cutting of the artificial entrance in 1889 stabilized lake levels and provided a permanent navigable pathway, it allowed lake salinities to increase. Before this event, most shorelines of the lakes were fringed with common reed (*Phragmites australis*) which not only promoted sedimentation but protected shores from wave action. *Phragmites* grows well in fresh and slightly brackish water but not in moderate salinities. With the increase in lake salinities, a large proportion of that protective vegetation has died, and about 75% of the shorelines of the lakes are eroding. In some places, up to 50 m of shore has been lost over 100 years. The Mitchell River delta is disintegrating despite the delivery of river sediments. By contrast, the Latrobe and Avon deltas in Lake Wellington, which is still almost fresh, are still growing, aided in part by the greater delivery of sediments due to modern agriculture.

The Gippsland Lakes are the best studied marine lagoons in Australia. Similar broad conditions characterize the numerous other marine inlets in western, southern, and eastern Australia, but there are interesting differences outlined by Bird (1967), Roy (1984), Timms (1992), and Kidd and Timms (2000).

GLACIER JÖKULHLAUP

Jónas Eliasson
 Reykjavík, Iceland

Definition

A jökulhlaup is an Icelandic word for a glacier outburst flood that has been adopted by the English language and is now used to describe any large and abrupt release of water from a subglacial or proglacial lake/reservoir.

Vatnajökull, Iceland, is the most famous source of jökulhlaups (Björnsson, 2003), especially the *Grímsvötn* caldera (geological term for a cauldron-like volcanic feature usually formed by the collapse of land following a volcanic eruption) (Björnsson, 2003) (Gudmundsson et al., 1995). The origin of the floods is water stored in a lake, dammed in by ice, that gives away and releases the impounded water in a sudden outburst (Johannesson, 2002). This can be due to lifting or braking of the ice dam or melting of a tunnel under the ice. The reason for the accumulation of water in the storage is often geothermal melting of ice or volcanic subglacial eruption, but accumulation in marginal lakes is also a known cause (Roberts et al., 2005). There is usually some kind of triggering mechanism that determines when the flood is released, this may be the lifting of the ice dam by water pressure, undermining of the ice dam by erosion (piping) or a combination of both, so the timing of the onset of the flood cannot be predicted accurately (Tweed, 2000). Jökulhlaups are more often than not, violent and life-threatening events that need to be monitored closely under disaster management.

Water accumulation

A geothermal area has a natural heat output that can typically be 1 MW/km²; this melts around 400,000 t/year. Hot springs, steam vents, and small volcanic eruptions can increase this figure tremendously. On top of that there may be inflow of melt water due to ablation of the glacier and groundwater flow through the subsoil under the glacier. In order to predict the accumulation process, complex hydrological and glaciological surveys are necessary. The bottom under the glacier and the thickness of the glacier itself has to be surveyed by echo soundings and topographical surveys (Björnsson, 1982). The subglacial watershed and the drainage channel network can be determined from this data (Etzelmueller and Björnsson, 2000). Snow- and ablation surveys have to be performed and mass balance of the glacier estimated. Then, the curves for the elevation versus area and storage volume of the reservoir have to be prepared and the change in reservoir storage pressure recorded. In this way, the jökulhlaup risk can be monitored and the civil defense authorities alerted in time.

Jökulhlaup hydraulics

The hydrograph of a jökulhlaup is typically triangular shaped. When it is melting of an ice tunnel that determines the flow rate, the maximum discharge will usually come late in the flood period. When the jökulhlaup has the character of a dam break flood, the maximum discharge comes early. In both cases, the maximum flood can be estimated if the baseline (time length) of the hydrograph is known. The flood will in both cases brake up the glacier margin and float numerous icebergs down the channel harassing roads, bridges, and all other obstacles in the channel. The area coverage of the flood itself can be determined

by the usual methods applied for dam break floods (Eliasson, 2008), provided the source hydrograph is known. The flood itself progresses down the channel network like a transitory flood (Eliasson et al., 2007). In practice, this means that the flood wave travels easily over dry land like a wall of water that can be several meters high; the velocity of the wall is so high that it cannot be outrun by animals or humans, very much like a tsunami that inundates a coast. The CFD (Computational Fluid Dynamics) models used in modeling the flood wave are usually two-dimensional models; they can be used to produce videos that show an aerial view of the flood wave as Figure 3 does. Such videos can be made to show the progression of the wave front, the velocity of it, the arial extent of the inundation (Alho et al., 2007), and the water depths. They are therefore a useful tool in planning civil protection tactics, rescue operations, and other parts of the disaster management plan.

Jökulhlaup statistics

The magnitude and frequency of jökulhlaups depends on the accumulation rate at the source and the reservoir characteristics. Climatically controlled jökulhlaups can be modeled and the cyclic frequency found (Ng and Liu, 2009) (Alho and Aaltonen, 2008). For volcanic jökulhlaups, statistical methods can be used to find the risk of having an event in the, e.g., next year or in another time period. It is not uncommon to find that the distribution of the time periods in between consecutive events is lognormally distributed (Eliasson et al., 2006). By building an appropriate stochastic model, the risk can be estimated. However, this risk will increase with time, so its magnitude will have to be updated regularly.

Occurrence of jökulhlaups

Prehistoric occurrences

Geological evidence of jökulhlaups can be found in almost every region that has been glaciated in prehistoric times. This is especially true for the last ice age in the northern hemisphere. The three best known examples in North America are firstly the Lake *Agassiz* that covered much of Manitoba, western Ontario, northern Minnesota, eastern North Dakota, and Saskatchewan; secondly Glacial Lake *Missoula* in western Montana; and thirdly Glacial Lake *Ojibway* in northern Ontario and Quebec, Canada. All three are responsible for tremendous outbursts in the period 13,000–8,000 BP. These events are all believed to have caused serious climatic impacts, e.g., the Younger Dryas climate period. However, there are many controversial theories about these flood events and their connection to serious climate changes, shifts in the Gulf Stream, deep sea formation in the North Atlantic, thermohaline circulation, and the Great Ocean Conveyor Belt. North Siberia is another region where geological evidence of similar floods has been unearthed (Carling et al., 2010); there are also reports from Scandinavia (Klingbjør, 2004).

Jökulhlaups in historical times

Today jökulhlaups occur in the regions where glaciers that are remnants of the last glaciation remain. Apart from Iceland, there are reports of jökulhlaups in, e.g., Antarctica (Peters et al., 2009), the Himalayas (Richardson and Reynolds, 2000), and northern Sweden (Klingbjør, 2004).

The hall of fame

There are two jökulhlaup sites in Iceland that attract a lot of attention, and many reports exist on them. The course of a jökulhlaup event is best described by studying them.

The Katla system

This is a 70-km³ caldera with associated flood channel system, located in *Mýrdalsjökull*, a glacier-covered mountain range in south Iceland, that reaches above an elevation of 1,500 m and is partly covered by the 200–700 m thick glacier which fills up a caldera and covers its eruptive vents. There are three volcanic craters under the glacier, one of them (*Kötlugjá*) has erupted regularly for the last 1,100 years. Geological evidence of earlier eruptions in the other two dates 6,000 years back in time. Katla jökulhlaups are exceptionally ferocious, sending a flood wave out to the sea that may reach a discharge of 300,000 m³/sand inundate the lowlands by up to 10 m of water. These jökulhlaups are by far the greatest floods experienced in the world in historical times; the last one occurred in 1918. It came from the easternmost volcano *Kötlugjá* (a little bit higher up than *Kötlujökull* in Figure 1). The other two are *Entujökull* just inside the westernmost rim of the caldera, and *Sólheimajökull* just inside the southwest rim of the caldera (Figure 1).

When there is an eruption, the ice over the crater is likely to be 400 m thick. The erupted mass has a temperature of 1,100–1,300°C, melts the ice very rapidly, and forms a cavity inside the glacier. Eventually the roof of the cavity will cave in, the eruption will reach above the water surface, and an eruption column will rise to a height of the order of magnitude 10 km and send volcanic ash and gasses into the atmosphere, causing significant poisoning of the air and all waters downwind of the eruption. Traces of gas and fine ash can be noticed many hundreds of kilometers away. Disruption of air traffic can be very severe; the Eyjafjallajökull event in April 2010 caused an economic loss of \$5 billion. The associated small jökulhlaup is marked by a blue arrow on Figure 1; it came from *Gígjökull*.

Figure 2 shows the results of the mapping techniques used in the investigations of jökulhlaups. The figure shows that in order to flow out of the caldera depression, the water has to flow over a threshold in pass carved in the mountain range by the glaciers. There are other passes that could be outlets, but the three outlets have the lowest thresholds. When the water flows over the thresholds, it breaks up the glacier in the channel and carries it as icebergs downstream. This combination of fast water flow and icebergs that can reach hundreds of tons is the reason for how destructive these floods are. They also carry a lot

Glacier Jökulhlaup, Figure 2 The Katla caldera with (top) and without (bottom) the glacier. The three outlet channels are shown (Echo sounding, mapping, and graphics by Helgi Björnsson, Finnur Pálsson, and Magnús T. Guðmundsson (2000)).

Glacier Jökulhlaup, Figure 3 Numerical simulation of the Entujökull jökulhlaup. *Top:* 9 h 13 min from the beginning of the event. *Bottom left:* 3 h 40 min. *Bottom right:* 2 h 00 min.

of pumice, sand, and gravel that by time form an alluvial plain, an example is seen on [Figure 3](#).

Several hundred people are living in the area, many more in the summer than in winter time. Numerical simulation is used to find the area inundated by the flood ([Figure 3](#)) in order to define the risk area. The Mýrdalsjökull is kept under close surveillance by the civil protection service; the rivers from the three glaciers are monitored for sudden flow augmentations and changes in chemical content, mainly hydrogen sulfide as it is a well-known magmatic gas. Seismicity is monitored as volcanic eruptions are preceded by earthquakes. There are however numerous earthquakes without any eruption, so the possibility of a false alarm is high ([Figure 4](#)).

The most dangerous flood wave is one in the west; the last one happened in 750 AD. Several hundred people live in the inundation area. These floods come with an average return period of 1000 years. The last eruption in 1918 was a big flood that occurred in the Kötlugjá (K). The overall average return based on the last 1,100 years of record is 50 years, so the probability for a flood in the

west is not very high. A long pause in the activity is likely when the last flood is as big as the 1918 event, and this complicates the statistics considerably, but it may be estimated that there is 50% probability for an eruption in the next 5 years. There are no reliable statistical estimates for the size of that eruption. Plans do exist for the evacuation of 2,000 people or more in a civil protection action when an eruption occurs.

The Grímsvötn-Skeidará system

Water accumulates steadily in the Grímsvötn caldera ([Figure 5](#)). The ice sheet covering the water is for the most part 100–200 m thick and gets lifted up according to the accumulation rate. This rate depends on three factors, geothermal activity in the caldera and the watershed surrounding it, groundwater/iceflow/precipitation creeping and percolating in (a minor factor) and then the very uncertain factor, and volcanic eruptions inside the caldera or elsewhere in the watershed. The most famous event of this last type is the Gjálp eruption in 1996. This was an event outside the caldera bottom, but all the meltwater flowed into

Glacier Jökulhlaup, Figure 4 The position of the three volcanoes in Myrdalsjökull with eruption probabilities in%. Values in circles are the probability that the next eruption will be in the same place as the last one. Values near the beginning of an *arrow* indicate the probability the next eruption will occur in the crater where the *arrow* ends.

Glacier Jökulhlaup, Figure 5 Topographical map of the Grímsvötn caldera. Elevations in meters. Grímsvötn is an ice-covered lake that is the flat area in the calderas *bottom*. Location in Vatnajökull shown in the *left bottom* corner picture.

Glacier Jökulhlaup, Figure 6 Rise and fall of the surface of Grímsvötn 1930–2002. Elevation in meters above sea level on the left-hand scale. Red marker, 1,450 m (Bjornsson 2003).

the lake inside the caldera. Eruptions inside the caldera that do not melt any ice that is not already floating have very little effect on the uplift of the lakes' ice cover. When the water can start flowing over the threshold, a jökulhlaup is impending. This water flow is a combined action of the water pressure lifting the ice on the threshold up and the water eroding its way through the sediments on the bottom by piping over the last barrier. As may be seen on the map, the ice surface drops steeply on the other side of the mountain *Grímsfjall*, so when water reaches such a location with the full pressure head of the lake, it can easily lift up the glacier and flow on. This it does only slowly to begin with, but little by little it melts a tunnel over the threshold, so the discharge increases as time goes until the ice sheet settles on the bottom and the waterflow stops.

Figure 6 shows that during a jökulhlaup event, the ice cover sinks suddenly down on the order of magnitude 100 m and then rises slowly again. Before 1940, there are two large jökulhlaups influenced by volcanic eruptions. In 1970, there is a small eruption inside the caldera that causes the next jökulhlaup event to come sooner than expected, but apart from this, the process is fairly regular in 1940–1995 with an average return period of little less than 6 years. During this time, the maximum flood diminished and the flood period lengthened. The 1996 Gjálp eruption was a very large event as the volcanic eruption outside the caldera and higher up in the glacier sent large quantities of melt water into the caldera and caused the ice cover to lift so rapidly that the process did not have time to develop in the usual manner and resulted in a flash flood. This event has clearly altered the old mechanism, so the floods have an entirely different character since. The flood water flowing over the Grímsvötn threshold travels then downhill under the ice for about 50 km and emerges through a glacial port of Skeidará river in the easternmost side of the *Skeidarárjökull* margin and floods the sands from there to the sea. The 1996 flood that reached a peak of 40,000 m³/s ruined three bridges and several hundred meters of road, but otherwise these floods do little damage in spite of the fact that the normal discharge of Skeidará is

multiplied and the floods carry with them a very high quantity of sand, gravel, and icebergs.

GREAT LAKE PROCESSES: THERMAL STRUCTURE, CIRCULATION AND TURBULENT DIFFUSION PROCESSES

Yerubandi R. Rao

Environment Canada, National Water Research Institute,
Canada Center for Inland Waters, Burlington, ON, Canada

Introduction

The Laurentian Great Lakes Basin is located along the international boundary between Canada and the United States. In extent the basin encompasses an area of 772,053 km². The Great Lakes comprise the largest volume of freshwater on earth. The system is comprised of five major lakes: Lake Superior, Michigan, Huron, Erie, and Ontario, which together occupy nearly one third of the total basin area ([Figure 1](#)). Flow from headwaters at Lake Superior to the final outflow into the Atlantic Ocean is continuous; water is transported through various connecting channels. With horizontal scales of hundreds of kilometers, depth scales of 100 m, and a well-developed seasonal thermal stratification in the summer, the Laurentian Great Lakes of North America are host to many of the physical phenomena associated with the coastal oceans or inland seas. The closed nature of the Great Lakes basins provides an excellent opportunity to study the Great Lakes systems as model oceans.

Seasonal thermal structure of the Great Lakes

The thermal structure in the Great Lakes generally depends on the season because of the large annual variation of surface fluxes ([Boyce et al., 1989](#)). With the exception of smaller Lake St. Clair and shallow western basin of Lake Erie, the Great Lakes are thermally stratified during the summer months. There are regional differences through the Great Lakes basin; full stratification may not occur until August in Lake Superior, whereas Lake Erie may be stratified by late May. The major differences between the oceans and the Great Lakes is a consequence of the equation of state for freshwater that shows a maximum density at 4°C. Thus convective overturning occurs both in fall and spring, making the lakes dimictic. The spring thermal bar is discussed more in this volume, so it is not discussed further here.

As the 4°C isotherm disappears from the surface to the deeper mid-lake, the thermal stratification progresses over the lake. The intensity of wind-induced turbulence determines the level to which the heat from solar radiation is mixed down, and hence, the thermocline tends to deepen during stormy periods. Isotherms drawn from a Lake Ontario model simulation is shown in [Figure 2](#). Surface heat losses and deep vertical mixing associated with large storms in the fall, result in the deepening of thermocline. A fall/winter thermal bar is noted on some occasions in the Great Lakes, followed by the coldest temperatures in February to early March in most of the Great Lakes.

Wind-driven circulation

The Great Lakes have complex velocity and scalar fields with a wide spectrum of dynamically important length scales ranging from circulation patterns of scales of 100 km down to small-scale turbulence of the order of millimeters. Superimposed on a mean flow circulation, these turbulent eddy-like motions exist in both horizontal and vertical directions. The scales of horizontal eddies, however, are much larger than those of vertical eddies because in the Great Lakes horizontal dimensions are greater than vertical dimensions. The Great Lakes manifest into two distinct flow environments: an open lake environment and a coastal environment. The main differences between these regions are that the momentum imparted by the wind stress is balanced by bottom friction inshore, while it is balanced by the Coriolis force offshore.

The prime driving force of circulation in the lakes is the wind ([Csanady, 1982](#)). [Betetsky et al. \(1999\)](#) compiled the mean circulation in the Great Lakes based on several experimental data sets conducted over the years ([Figure 3](#)). They noted that during the unstratified period (November–June), storm action is the most important forcing, as higher wind speeds and the absence of stratification allow the wind forcing to penetrate deeper into the water column. Storm-induced currents in the Great Lakes can be quite strong (up to several tens of cm/s), but the average (seasonal means) currents are rather weak throughout most seasons of the year (on the order of only a few cm/s). The average magnitude of summer circulation in the Great Lakes is 1.0–2.4 cm/s, while mean summer currents can be as small as 0.1 cm/s at certain locations and the maximum current speed can reach up to 7 cm/s. Currents typically change their direction with depth, and their speed decreases, which reflects the importance of baroclinic effects in the presence of the seasonal thermocline. The summer circulation pattern is mostly cyclonic in the upper Great Lakes, whereas the anticyclonic gyre dominates and only a smaller cyclonic gyre is present in the western part in Lake Erie. In Lake Ontario the cyclonic circulation in the central part is a dominant feature with stronger eastward current near the south shore. The Keweenaw current is a persistent feature of summer circulation in Lake Superior. Cyclonic circulation persists in the winter. Winter currents are generally

Great Lake Processes: Thermal Structure, Circulation and Turbulent Diffusion Processes, Figure 1 A map of the Laurentian (North American) Great Lakes.

stronger than summer currents, and, therefore, annual circulation patterns closely resemble winter circulation patterns.

In the coastal regions, the wind action rapidly generates flow predominantly parallel to the coast. The coast prevents perpendicular movement, but longshore motion is unhindered and the longshore component of the wind is particularly effective in generating longshore currents and corresponding long particle displacements. However, winds at mid-latitudes are variable, rarely remaining constant for more than a day. Under these circumstances the transient properties of currents are often of greater practical importance than the steady state for constant wind. These transient properties depend on inertial forces.

Climatological aspects of coastal currents were developed in parts of Lake Ontario by employing carefully conducted field experiments. In general, the energy spectra of currents have broad peaks at around 10–12 days coinciding with basin scale response to meteorological forcing, and a spectral minimum at around 24–30 h. The dominant peak near 17 h corresponds to the near-inertial period of Lake Ontario, and increases in offshore

direction. The near-inertial oscillations, which are mainly due to large internal waves, are characteristic features of summer stratification and are observed to be intermittent in most of the lakes. The spectral minimum at 24–30 h was used for energy transfer from large-scale lake-wide circulation to small-scale oscillations for delineating mean flows and fluctuations. Also in the range of frequencies between Coriolis frequency and maximum Brunt-Vaisala frequency turbulent eddies are intermingled with near-inertial internal waves and the motions in this range are generally classified as mesoscale turbulent motions.

Horizontal diffusion

Horizontal exchange of heat, energy, and momentum occur at scales generally much larger than vertical exchanges, given the large horizontal lengths of natural basins compared to their depths. This has prompted many researchers to decouple horizontal transfers from vertical ones, even though horizontal and vertical processes interact. Numerous dye studies and tracer experiments conducted to determine the diffusion characteristics of the water column also show that the vertical exchange

Great Lake Processes: Thermal Structure, Circulation and Turbulent Diffusion Processes, Figure 2 Modeled annual cycle of vertical temperature structure in Lake Ontario.

Great Lake Processes: Thermal Structure, Circulation and Turbulent Diffusion Processes, Figure 3 Mean circulation in the Great Lakes (Source: Betetsky et al., 1999).

coefficient is much smaller than the horizontal counterparts. Here, we illustrate the nature of horizontal diffusion characteristics in the Great Lakes from a set of carefully conducted field experiments with (1) fluorescent dye studies (2) satellite tracked Lagrangian drifters, and (3) using point current meters or acoustic Doppler current profilers.

Tracer experiments

When a marked tracer is released into a turbulent environment such as oceanic coastal currents, the subsequent transport and diffusion of the tracer may be studied either in a frame of reference moving with the center of gravity of the plume or in a frame of reference fixed to the stationary source. Conventionally the former is referred to as

relative diffusion and the latter as absolute diffusion. The interlink between the two concepts is explained by the random movements of the center of gravity of the diffusing plume usually referred to as the meandering. One may regard absolute diffusion as a superposition of the two component processes of relative diffusion, i.e., diffusion relative to the center of gravity of the plume and meandering or bodily displacements of the diffusing plume parcels. In studies of turbulent diffusion in the natural environment, both formulations have been applied.

Experimental data from large-scale field diffusion studies in the Great Lakes have contributed a great deal to examine critically the dependence of the horizontal diffusion process on the properties of turbulent eddies.

Richardson's 4/3 power law has been the basis to interpret natural environmental diffusion data and results in view of the widely accepted physical basis on which it is derived by applying the concepts of the similarity theory of turbulence. In the inertial subrange the similarity theory predicts that the turbulent kinetic-energy spectrum $E(k)$ is given by the familiar $-5/3$ power law:

$$E(k) = c\varepsilon^{2/3}k^{-5/3} \quad (1)$$

where c is a universal dimensionless constant; ε is the rate of dissipation of turbulent kinetic energy, and k is the wave number.

We assume that turbulent eddies larger than the size of the diffusing cloud does not contribute much to the diffusion process. Furthermore, if we designate a length scale $\iota = k^{-1}$ to the eddies responsible for the diffusion of the cloud, then for a point source initially released into a turbulent medium consisting of a spectrum of eddies of several sizes, the turbulent kinetic energy available for diffusion of the cloud would be:

$$\overline{q^2} \propto \int_k^\infty \partial(k) dk \quad (2)$$

Combining (1) and (2) the turbulent velocity associated with length scale, ℓ , is given by:

$$\overline{q^2}^{1/2} = c\varepsilon^{1/3}\ell^{1/3} \quad (3)$$

Following mixing length arguments an effective horizontal diffusivity of the diffusion process can be defined by:

$$K = \text{const}\varepsilon^{1/3}\ell^{-4/3} \quad (4)$$

which is the Richardson's 4/3 power law of diffusion. The physical meaning of the Richardson's 4/3 power law is that the inertial subrange eddies are active and the diffusion process is characterized by two parameters: ε , the rate of turbulent energy dissipation and ℓ the length scale of eddies.

Experimental diffusion data from Lake Ontario and some parts of the oceans validate the Richardson's 4/3 power law of diffusion quite well. Figure 4 shows on logarithmic scale the effective diffusivity versus the length scale of diffusion from experimental diffusion data obtained in widely varying environmental conditions in the oceanic and aquatic environments (Murthy, 1976). The dependence of the effective diffusivity on the length scale provides useful guidelines for modeling of practical diffusion problems in the natural environment.

Lagrangian drifter experiments

Drifters have been used to study particle dispersion by oceanic turbulence since the early work of Stommel. Since that time drifter trajectories have been obtained for a wide

Great Lake Processes: Thermal Structure, Circulation and Turbulent Diffusion Processes, Figure 4 Horizontal eddy diffusivity as a function of length scale of diffusion field.

range of length and timescales. It quickly became apparent that eddy diffusion in oceans and lakes is not Fickian. Taylor (1921) showed that, in a stationary homogeneous turbulence, particle dispersion is related to Lagrangian integral timescales. In a study using drifter trajectories in an experiment conducted in Lake Ontario for two different flows, Lagrangian timescale, and eddy diffusion coefficients were calculated. The Lagrangian integral timescale (T_i^L) and length scale (L_i^L) are the time and distance over which the drifter motion remains correlated:

$$T_i^L = \int_0^T R_{ii}^L(\tau) d\tau \text{ and } L_i^L = \sqrt{\langle u_i'^2 \rangle} \int_0^T R_{ii}^L(\tau) d\tau. \quad (5)$$

Here, R_{ii}^L is the autocorrelation function defined as:

$$R_{ii}^L(\tau) = \frac{1}{T} \frac{\int_0^{T-\tau} u_i'(t) u_i'(t+\tau) dt}{\langle u_i'^2 \rangle} \quad (6)$$

where u' is the residual velocity defined by $u' = u - \langle u \rangle$, $\langle u \rangle$ denotes average over time. Further, it was observed that because of low-frequency motions, Lagrangian integral time and length scales are generally time dependent and do not approach a constant limit. Most of the individual autocorrelation functions oscillate and have significant

lobes, which underestimate the integral timescale as they are integrated over the duration of the time series. To avoid this, studies in the Great Lake integrate from zero to the time of first zero crossing.

By assuming that the drifter velocity fluctuations are homogeneous and stationary as a first-order approximation, we can write the mean squared dispersion due to single-particle motion as:

$$\langle x_i'^2 \rangle = 2 \langle u_i'^2 \rangle \int_0^t (t - \tau) R_{ii}^L(\tau) d\tau \quad (7)$$

When diffusion time elapses beyond some lag time t_ℓ (Lagrangian correlation timescale), $R_{ii}^L(\tau)$ will drop to zero. Physically t_ℓ is the decay timescale of those eddies which contributes to diffusion. Therefore, for large timescales $t > t_\ell$ the horizontal eddy exchange coefficient is given by:

$$K_i^L = \langle u_i'^2 \rangle T_i^L \quad (8)$$

Eulerian experiments

In a stationary and homogeneous turbulence, the Lagrangian variance $\langle u_L'^2 \rangle$ can be assumed to be equivalent to Eulerian variance $\langle u_e'^2 \rangle$. Hay and Pasquill (1959) pointed out that the essential difference between Eulerian and Lagrangian velocities is that, at a fixed point, velocity fluctuations appear to move rather quickly, as turbulent eddies are advected past the instrument. They have shown that the Lagrangian correlation function $R_{ii}^L(\tau)$ and the Eulerian counterpart $R_e(\tau)$ have a similar shape but differ only by a factor β , which is greater than unity: $R_e(\tau) = R_{ii}^L(\beta\tau)$. Introducing these assumptions, the horizontal exchange coefficient in terms of Eulerian statistics can be written as:

$$K_e = \beta \langle u_e'^2 \rangle T_e \quad (9)$$

where T_e is the Eulerian integral timescale.

The autocorrelations for Lagrangian and Eulerian currents showed a number of interesting features (Rao and Murthy, 2001). In Lake Ontario the autocorrelations of filtered Lagrangian velocities have fallen to near zero values for all drifters within 8–12 h, and have shown peaks at 14-h periodicity. The filtered Eulerian values showed a steady drop of alongshore autocorrelations, whereas cross-shore autocorrelations showed a peak at a period of 24 h. Lagrangian timescales (τ_L) estimated from autocorrelations were less than Eulerian timescales (τ_e). This was attributed to the affect of total acceleration in Lagrangian measurements which includes advection, whereas Eulerian timescales were only a function of local acceleration. This indicates the nonlinearity of the evolution of time-varying currents. In Great Lakes the value of $\beta = 1.4$ has been used to calculate Eulerian exchange coefficients. In general, alongshore exchange coefficients

(K_x) were slightly higher than cross-shore components (K_y) in the first 5.5 km from the shore. The cross-shore components reached a peak at around 6–7 km from shore and remained steady outside the coastal boundary layer. The studies in the Great Lakes indicate that momentum transfers occur in the longshore direction in the near coastal areas and cross-shore transfers may dominate in a zone where mid-lake motions adjust to shoreline. Although the magnitude of alongshore Lagrangian eddy coefficients were higher than Eulerian values, they showed a peak nearly at the same distance. The cross-shore exchange coefficients in the surface levels were in general lesser than subsurface values.

Vertical mixing

Several mechanisms such as current shear, breaking of internal waves, or convective overturns contribute to the generation of vertical turbulence in lakes and coastal oceans. The strong influence that the vertical shear and stability have on turbulence can be estimated from the gradient Richardson number, $Ri = N^2/S^2$. Here, N is the Brunt-Vaisala frequency given as $N^2 = -\frac{g}{\rho_0} \frac{\partial \rho}{\partial z}$ and the vertical current shear $S^2 = \left(\frac{\partial u}{\partial z}\right)^2 + \left(\frac{\partial v}{\partial z}\right)^2$, where, z is the vertical coordinate positive upward, u and v are hourly cross-shore and alongshore currents, respectively, g is the acceleration due to gravity, and ρ_0 is reference density. Although, the turbulent mixing can be calculated on the basis of different models, simple models employing Richardson number have been quite popular in the Great Lakes.

In general, current shear in the upper mixed layer was closely related to the wind stress. In Lake Ontario during a full upwelling episode, N dropped to small values ($< 2.0 \times 10^{-2}$) and the vertical shear was weak all through the water column because of nearly homogeneous conditions. Because of low values of N , a weak current shear was sufficient to reduce Richardson numbers to near-critical values (< 0.25) in the upper mixed layer thus enhancing the turbulence. Part of this enhanced turbulence has resulted in increasing the vertical eddy viscosity coefficients ($30\text{--}40 \text{ cm}^2 \text{ s}^{-1}$) during this episode. On the other hand, downwelling episodes produced low N in the upper mixed layer, and much higher values in the bottom layers. This was due to a deepening of the mixed layer and the migration of thermocline close to the bottom. Vertical current shears slightly increased at a depth of 8–9 m at the base of the mixed layer. This slightly reduced the Richardson number and enhanced mixing at that level.

GREAT LAKES, NORTH AMERICA

Reginald W. Herschy

Hydrology Consultant, Reading, UK

Introduction

The Great Lakes – Superior, Michigan, Huron, Erie, and Ontario – are an important part of the physical and cultural heritage of North America. Spanning more than 1,200 km (750 miles) from west to east, these vast inland freshwater seas have provided water for consumption, transportation power, recreation, and a host of other uses ([Plate 1](#)).

The water of the lakes and the many resources of the Great Lakes basin have played a major role in the history and development of the USA and Canada. For the early European explorers and settlers, the lakes and their tributaries were the avenues for penetrating the continent, extracting valued resources, and carrying local products abroad. Now the Great Lakes basin is home to more than one-tenth of the population of the USA and one-quarter of the population of Canada. Some of the world's largest concentrations of industrial capacity are located in the Great Lakes region. Nearly 25% of the total Canadian agricultural production and 7% of the American production are located in the basin. The USA considers the Great Lakes a fourth seacoast, and the Great Lakes region is a dominant factor in the Canadian industrial economy.

Physical characteristics of the system

The magnitude of the Great Lakes water system is difficult to appreciate, even for those who live within the basin. The lakes contain about 23,000 km³ (5,500 cu. ml.) of water, covering a total area of 244,000 km² (94,000 square miles). The Great Lakes are the largest system of fresh, surface water on earth, containing roughly

18% of the world supply. Only the polar ice caps contain more fresh water ([Table 1](#)).

In spite of their large size, the Great Lakes are sensitive to the effects of a wide range of pollutants. The sources of pollution include the runoff of soils and farm chemicals from agricultural lands, the waste from cities, discharges from industrial areas, and leachate from disposal sites. The large surface area of the lakes also makes them vulnerable to direct atmospheric pollutants that fall with rain or snow and as dust on the lake surface.

Outflows from the Great Lakes are relatively small (less than 1% per year) in comparison with the total volume of water. Pollutants that enter the lakes – whether by direct discharge along the shores through tributaries, from land use, or from the atmosphere – are retained in the system and become more concentrated with time. Also pollutants remain in the system because of resuspension (or mixing back into the water) of sediment and cycling through biological food chains.

Because of the large size of the watershed, physical characteristics such as climate, soils, and topography vary across the basin. To the north, the climate is cold and the terrain is dominated by a granite bedrock called the Canadian (or Laurentian) Shield consisting of Precambrian rocks under a generally thin layer of acidic soils. Conifers dominate the northern forests.

In the southern areas of the basin, the climate is much warmer. The soils are deeper with layers or mixtures of clays, silts, sands, gravels, and boulders deposited as glacial drift or as glacial lake and river sediments. The lands are usually fertile and can be readily drained for agriculture. The original deciduous forests have given way to agriculture and sprawling urban development.

Although part of a single system, each lake is different. In volume, Lake Superior is the largest. It is also the deepest and coldest of the five. Superior could contain all the other Great Lakes and three more Lake Eries. Because of its size, Superior has a retention time of 191 years. Retention time is a measure based on the volume of water in the lake and the mean rate of outflow. Most of the Superior basin is forested, with little agriculture because of a cool climate and poor soils. The forests and sparse population result in relatively few pollutants entering Lake Superior, except through airborne transport.

Lake Michigan, the second largest, is the only Great Lake entirely within the USA. The northern part is in the colder, less developed upper Great Lakes region. It is sparsely populated, except for the Fox River Valley, which drains into Green Bay. This bay has one of the most productive Great Lakes fisheries but receives the wastes from the world's largest concentration of pulp and paper mills. The more temperate southern basin of Lake Michigan is among the most urbanized areas in the Great Lakes system. It contains the Milwaukee and Chicago metropolitan areas. This region is home to about eight million people or about one-fifth of the total population of the Great Lakes basin.

Lake Huron, which includes Georgian Bay, is the third largest of the lakes by volume. Many Canadians and

Great Lakes, North America, Plate 1 Michigan.

Americans own cottages on the shallow, sandy beaches of Huron and along the rocky shores of Georgian Bay. The Saginaw River basin is intensively farmed and contains the Flint–Saginaw–Bay City metropolitan areas. Saginaw Bay, like Green Bay, contains a very productive fishery.

Lake Erie is the smallest of the lakes in volume and is exposed to the greatest effects from urbanization and agriculture. Because of the fertile soils surrounding the lake, the area is intensively farmed. The lake receives runoff from the agricultural area of southwestern Ontario and parts of Ohio, Indiana and Michigan. Seventeen metropolitan areas with populations over 50,000 are located within the Lake Erie basin. Although the area of the lake is about 26,000 km² (10,000 square miles), the average depth is only about 19 m (62 ft), the shallowest of the five lakes, and therefore warms rapidly in the spring and summer and frequently freezes over in winter. It also has the shortest retention time of the lakes, 2.6 years. The western

basin, comprising about one-fifth of the lake, is very shallow with an average depth of 7.4 m (24 ft) and a maximum depth of 19 m and 62 ft.

Lake Ontario, although slightly smaller in area, is much deeper than its upstream neighbor, Lake Erie, with an average depth of 86 m (283 ft) and a retention time of about 6 years. Major urban industrial centers, such as Hamilton and Toronto, are located on its shore. The US shore is less urbanized and is not intensively farmed, except for a narrow band along the lake.

Settlement

The modern history of the Great Lakes region, from discovery and settlement by European immigrants to the present day, can be viewed not only as a progression of intensifying use of a vast natural resource but also as a process of learning about the Great Lakes ecosystem. At first, it was a matter of making use of the natural

resources of the basin while avoiding its dangers. Not until much later, when the watershed was more intensively settled and exploited, was it learned that abuse of the waters and the basin could result in great damage to the entire system.

Exploitation

The first Europeans found a relatively stable ecosystem which had evolved during the 10,000 years since the retreat of the last glacier; a system that was only moderately disturbed by the hunting and agricultural activities of the native peoples. The first European arrivals had a modest impact on the system limited to the exploitation of some fur-bearing animals. However, the following waves of immigrants logged, farmed, and fished commercially in the region, bringing about profound ecological changes. The mature forests were clear-cut from the

watersheds, soil was laid bare by the plow, and the undisturbed fish population were harvested indiscriminately by an awesome new predator – humans with nets.

As settlement and exploitation intensified, portions of the system were drastically changed. Logging removed protective shade from streams and left them blocked with debris. Sawmills left streams and embayments clogged with sawdust. When the land was plowed for farming, the exposed soils were washed away more readily, burying valuable stream and river mouth habitats. Exploitive fishing began to reduce the seemingly endless abundance of fish stocks, and whole populations of fish began to disappear.

Industrialization

Industrialization followed close behind agrarian settlement, and the virtually untreated wastes of early industrialization

degraded one river after another. The growing urbanization that accompanied industrial development added to the degradation of water quality, creating nuisance conditions such as bacterial contamination, putrescence, and floating debris in rivers and nearshore areas. In some situations, the resulting contaminated drinking water and polluted beaches contributed to fatal human epidemics of water-borne diseases such as typhoid fever. Nonetheless, the problems were perceived as being local in nature.

As industrialization progressed, and as agriculture intensified after the turn of the twentieth century, new chemical substances came into use, such as PCBs (polychlorinated biphenyls) in the 1920s and DDT (dichloro-diphenyl-trichloroethane) in the 1940s. Non-organic fertilizers were used to enrich the already fertile soils to enhance production. The combination of synthetic fertilizers, existing sources of nutrient-rich organic pollutants, such as untreated human wastes from cities, and phosphate detergents caused an acceleration of biological production (eutrophication) in the lakes.

In the 1950s, Lake Erie showed the first evidence of lake-wide eutrophic imbalance with massive algal blooms and the depletion of oxygen.

The evolution of great lakes management

In the late 1960s, growing public concern about the deterioration of water quality in the Great Lakes stimulated new investment in pollution research, especially the problems of eutrophication and DDT. Governments responded to the concern by controlling and regulating pollutant discharges and assisting with the construction of municipal sewage treatment works. This concern was formalized in the first Great Lakes Water Quality Agreement between Canada and the USA in 1972.

Major reductions were made in pollutant discharges in the 1970s. The results were visible. Nuisance conditions occurred less frequently as floating debris and oil slicks began to disappear. Dissolved oxygen levels improved, eliminating odor problems. Many beaches reopened as a result of improved sewage control, and algal mats disappeared as nutrient levels declined. The initiatives of the 1970s showed that improvements could be made and provided several important lessons beyond the cleanup of localized nuisance conditions.

First, the problem of algal growth in the lakes caused by accelerated eutrophication required a lake-wide approach to measure the amount of the critical nutrient, phosphorus, entering and leaving each lake from all sources and outlets. This approach of calculating a "mass balance" of the substance was then combined with other research and mathematical modeling to set target loading limits for phosphorus entering the lake (or portions of the lake). The target load is the amount of phosphorus that will not cause excessive algal growth (i.e., an amount that could safely be assimilated by the ecosystem).

Other major lessons learned about the system resulted from research on toxic substances, initially the pesticide DDT. Toxic contaminants include persistent organic

chemicals and metals. These substances enter the lakes directly from discharges of sewage and industrial effluents and indirectly from waste sites, diffuse land runoff, and atmospheric deposition. As a result of increased research, sampling, and surveillance, toxic substances have been found to be a system-wide problem.

Toxic contaminants

Toxic contaminants pose a threat not only to aquatic and wildlife species but to human health as well. Since humans are at the top of many food chains, some toxic substances biologically accumulate or are magnified as they move through the food chain. Consequently, top predators such as lake trout and fish eating birds – cormorants, ospreys, and herring gulls – can receive extremely high exposures to these contaminants. Concentrations of toxic substances can be millions of times higher in these species than in water. As a result, the potential for human exposure to these contaminants is far greater from consumption of contaminated fish and wildlife than from drinking water.

Aquatic and wildlife species have been intensively studied, and adverse effects such as cross-bills and egg-shell thinning in birds and tumors in fish are well documented. There is less certainty about the risk to human health of long-term exposure to low levels of toxic pollutants in the lakes, but there is no disagreement that the risk to human health will increase if toxic contaminants continue to accumulate in the Great Lakes ecosystem. Long-term, low-level exposures are of concern because of subtle effects that toxic contaminants may have on reproduction, the immune system, and development in children. Relationships between environmental contaminants and diseases such as cancer are also of concern.

Understanding the lakes from an ecosystem perspective

The ecosystem approach, together with an increased emphasis on toxic substances, was given formal recognition in the second Great Lakes Water Quality Agreement signed in 1978. In 1987, management aspects of the ecosystem approach were further defined in revisions to the Agreement, calling for management plans to restore 14 beneficial uses. The beneficial uses to be restored include unimpaired use of the ecosystem by all living components, including humans.

The Agreement called for Remedial Action Plans (RAPs) to be prepared for geographic Areas of Concern (AOC) where local use impairments exist. It also called for Lakewide Management Plans to be prepared for critical pollutants that affect whole lakes or large portions of them. The purpose of these management plans is to clearly identify the key steps needed to restore and protect the lakes.

To measure restoration of ecosystem recovery, the 1987 Agreement revisions added a call for ecosystem objectives and indicators to complement the chemical objectives already provided in the Agreement. These biological measures of ecosystem integrity provide an important element

of the ecosystem approach and are being developed as part of the process for developing lake-wide management plans. Ecosystem indicators have already been adopted for Lake Superior. These indicators are organisms such as bird or fish populations that tell us whether the ecosystem is healthy and whether these populations are stable and self-reproducing.

The concepts of mass balance, system-wide contamination, and bioaccumulation in the food chain have become essential components in understanding the lakes from an ecosystem perspective. For example, the mass balance approach to phosphorus control has been used to formulate target pollutant loadings for the lower lakes.

Over 33 million people who live in the Great Lakes basin and their governments face an immense challenge for the future of the basin. The wise management needed to maintain the use of Great Lakes resources requires greater public awareness, the forging of political will to protect the lakes, and creative government action and cooperation.

The Great Lakes are surrounded by two sovereign nations, a Canadian province, eight American states, and thousands of local, regional, and special-purpose governing bodies with jurisdiction for management of some aspects of the basin or the lakes. Cooperation is essential because problems such as water consumption, diversions, lake levels, and shoreline management do not respect political boundaries.

With this in mind, public consultations that include residents, private organizations, industry, and government are considered to be an essential part of the decision-making process for managing the resources of the Great Lakes ecosystem. Residents of the basin have been empowered to participate in the problem-solving process, promote healthy sustainable environments, and reduce their personal exposure to Great Lakes contaminants.

Humans are part of and depend on the natural ecosystem of the Great Lakes but may be damaging the capacity of the system to renew and sustain itself and the tile within it. Protection of the lakes for future use requires a greater understanding of how past problems developed, as well as continued remedial action to prevent further damage.

Geology

The foundation for the present Great Lakes basin was set about 3 billion years ago during the Precambrian Era. This era occupies about five-sixths of all geological time and was a period of great volcanic activity and tremendous stresses, which formed great mountain systems. Early sedimentary and volcanic rocks were folded and heated into complex structures – these were later eroded and today appear as the gently rolling hills and small mountain remnants of the Canadian Shield, which forms the northern and north-western portions of the Great Lakes basin. Granitic rocks of the shield extend southward beneath the Paleozoic sedimentary rocks where they form the “basement” structure of the southern and eastern portions of the basin.

With the coming of the Paleozoic Era, most of central North America was flooded again and again by marine seas, which were inhabited by a multitude of life forms, including corals, crinoids, brachiopods, and mollusks. The seas deposited lime silts, clays, sand, and salts, which eventually consolidated into limestone, shales, sandstone, halite, and gypsum.

During the Pleistocene Epoch, the continental glaciers repeatedly advanced over the Great Lakes region from the north. The first glacier began to advance more than a million years ago. As they inched forward, the glaciers, up to 2,000 m thick, scoured the surface of the earth, leveled the hills, and altered forever the previous ecosystem. Valleys created by the river systems of the previous era were deepened and enlarged to form the basins for the Great Lakes. Thousands of years later, the climate began to warm, melting and slowly shrinking the glacier. This was followed by an interglacial period during which vegetation and wildlife returned. The whole cycle was repeated several times.

Sand, silt, clay, and boulders deposited by the glaciers occur in various mixtures and forms. These deposits are collectively referred to as “glacial drift” and include features such as moraines, which are linear mounds of poorly scoured material or “till,” flat till plains, till drumlins, and eskers formed of well-sorted sands and gravels deposited from meltwater. Areas having substantial deposits of well-sorted sands and gravels (eskers, kames, and outwash) are usually significant groundwater storage and transmission areas or aquifers. These also serve as excellent sources of sand and gravel for commercial extraction.

As the glacier retreated, large volumes of meltwater occurred along the front of the ice. Because the land was greatly depressed at this time from the weight of the glacier, large glacial lakes formed. These lakes were much larger than the present Great Lakes. Their legacy can still be seen in the form of beach ridges, eroded bluffs, and flat plains located hundreds of meters above present lake levels. Glacial lake plains known as “lacustrine plains” occur around Saginaw Bay and west and north of Lake Erie.

As the glacier receded, the land began to rise. This uplift (at times relatively rapid) and the shifting ice fronts caused dramatic changes in the depth, size, and drainage patterns of the glacial lakes. Drainage from the lakes occurred variously through the Illinois River Valley (toward the Mississippi River), the Hudson River Valley, the Kewartha Lakes Trent River, and the Ottawa River Valley before entering their present outlet through the St. Lawrence River Valley. Although the uplift has slowed considerably, it is still occurring in the northern portion of the basin. This, along with changing long-term weather patterns, suggests that the lakes are not static and will continue to evolve.

Climate of the great lakes

The weather in the Great Lakes basin is affected by three factors: air masses from other regions, the location of the basin within a large continental landmass, and the

moderating influence of the lakes themselves. The prevailing movement of air is from the west. The characteristically changeable weather of the region is the result of alternating flows of warm air from the Gulf of Mexico and cold, dry air from the Arctic.

In summer, the northern region around Lake Superior generally receives cool, dry air masses from the Canadian northwest. In the south, tropical air masses originating in the Gulf of Mexico are most influential. As the Gulf air crosses the lakes, the bottom layers remain cool while the top layers are warmed. Occasionally, the upper layer traps the cooler air below, which in turn traps moisture and airborne pollutants and prevents them from rising and dispersing (temperature inversion). This can result in dank, humid days in areas in the midst of the basin, such as Michigan and Southern Ontario, and can also cause smog in low-lying industrial areas.

Increased summer sunshine warms the surface layer of water in the lakes, making it tighter than the colder water below. In the fall and winter months, release of the heat stored in the lakes moderates the climate near the shores of the lakes. Parts of Southern Ontario, Michigan, and western New York enjoy milder winters than similar mid-continental areas at lower latitudes.

In the autumn, the rapid movement and occasional clash of warm and cold air masses through the region produce strong winds. Air temperatures begin to drop gradually, and less sunlight, combined with increased cloudiness, signals more storms and precipitation. Late autumn storms are often the most perilous for navigation and shipping on the lakes.

In winter, the Great Lakes region is affected by two major air masses. Arctic air from the northwest is very cold and dry when it enters the basin but is warmed and picks up moisture traveling over the comparatively warmer lakes. When it reaches the land, the moisture condenses as snow, creating heavy snowfalls on the lee side of the lakes in areas frequently referred to as snowbelts. For part of the winter, the region is affected by Pacific air masses that have lost much of their moisture crossing the western mountains. Less frequently, air masses enter the basin from the southwest, bringing in moisture from the Gulf of Mexico. This air is slightly warmer and more humid. During the winter, the temperature of the lakes continues to drop. Ice frequently covers Lake Erie but seldom fully covers the other lakes.

Spring in the Great Lakes region, like autumn, is characterized by variable weather. Alternating air masses move through rapidly, resulting in frequent cloud cover and thunder storms. By early spring, the warmer air and increased sunshine begin to melt the snow and lake ice, starting again the thermal layering of the lakes. The lakes are slower to warm than the land and tend to keep adjacent land areas cool, thus prolonging cool conditions sometimes well into April. Most years, this delays the leafing and blossoming of plants, protecting tender plants, such as fruit trees, from late frosts. This extended state of dormancy allows plants from somewhat warmer climates to

survive in the western shadow of the lakes. It is also the reason for the presence of vineyards in those areas.

Climate change and the great lakes

At various times throughout its history, the Great Lakes basin has been covered by thick glaciers and tropical forests, but these changes occurred before humans occupied the basin. Present-day concern about the atmosphere is premised on the belief that society at large, through its means of production and modes of daily activity, especially by ever increasing carbon dioxide emissions, may be modifying the climate at a rate unprecedented in history.

The very prevalent greenhouse effects are actually a natural phenomenon. It is a process by which water vapor and carbon dioxide in the atmosphere absorb heat given off by the earth and radiate it back to the surface. Consequently, the earth remains warm and habitable (16°C average world temperature rather than -18°C without the greenhouse effect). However, humans have increased the carbon dioxide present in the atmosphere since the industrial revolution from 280 ppm to the present 350 ppm, and some predict that the concentration will reach twice its pre-industrial levels by the year 2500.

Climatologists, using the General Circulation Model (GCM), have been able to determine the manner in which the increase of carbon dioxide emissions will affect the climate in the Great Lakes basin. Several of these models exist and show that at twice the carbon dioxide level, the climate of the basin will be warmer by 2–4°C and slightly damper than at present. For example, Toronto's climate would resemble the present climate of southern Ohio. Warmer climates mean increased evaporation from the lake surfaces and evapotranspiration from the land surface of the basin. This in turn will augment the percentage of precipitation that is returned to the atmosphere. Studies have shown that the resulting net basin supply, the amount of water contributed by each lake basin to the overall hydrological system, will be decreased by 23–50%. The resulting decreases in average lake levels will be from half a meter to 2 m, depending on the GCM used.

Large declines in lake levels would create large-scale economic concern for the commercial users of the water system. Shipping companies and hydroelectric power companies would suffer economic repercussions, and harbors and marinas would be adversely affected. While the precision of such projections remains uncertain, the possibility of their accuracy embraces important long-term implications for the Great Lakes.

The potential effects of climate change on human health in the world's lakes are of concern not least in the Great Lakes region, and researchers can only speculate as to what might occur. For example, weather disturbances, drought, and changes in temperature and growing season could affect crops and food production in the basin. Changes in air pollution patterns as a result of climate change could affect respiratory health, causing asthma, and new disease vectors and agents could migrate into the region.

The hydrological cycle

Water is a renewable resource (Plate 2). It is continually replenished in ecosystems through the hydrological cycle. Water evaporates in contact with dry air, forming water vapor. The vapor can remain as a gas, contributing to the humidity of the atmosphere, or it can condense and form water droplets, which, if they remain in the air, form fog and clouds. In the Great Lakes basin, for example, much of the moisture in the region evaporates from the surface of the lakes. Other sources of moisture include the surface of small lakes and tributaries, moisture on the land mass, and water released by plants. Global movements of air also carry moisture into the basin, especially from the tropics.

Moisture-bearing air masses move through the Great Lakes basin and deposit their moisture as rain, snow, hail, or sleet. Some of this precipitation returns to the atmosphere, and some falls on the surfaces of the Great Lakes

to become part of the vast quantity of stored fresh water once again. Precipitation that falls on the land returns to the lakes as surface runoff or infiltrates the soil and becomes groundwater.

Whether it becomes surface runoff or groundwater depends upon a number of factors. Sandy soils, gravels, and some rock types in the basin contribute to groundwater flows, whereas clays and impermeable rocks contribute to surface runoff. Water falling on sloped areas tends to run off rapidly, while water falling on flat areas tends to be absorbed or stored on the surface. Vegetation also tends to decrease surface runoff; root systems hold moisture-laden soil readily, and water remains on plants.

Surface runoff

Surface runoff is a major factor in the character of the Great Lakes basin. Rain falling on exposed soil tilled for agriculture or cleared for construction accelerates erosion

Great Lakes, North America, Plate 2 The Great Lakes Water System.

and the transport of soil particles and pollutants into tributaries. Suspended soil particles in water are deposited as sediment in the lakes and often collect near the mouths of tributaries and connecting channels. Much of the sediment deposited in nearshore areas is resuspended and carried farther into the lake during storms. The finest particles, clays and silts, may remain in suspension long enough to reach the mid-lake areas.

Before settlement of the basin, streams typically ran clear year-round because natural vegetation prevented soil loss. Clearing of the original forest for agriculture and logging has resulted in both more erosion and runoff into the streams and lakes. This accelerated runoff aggravates flooding problems.

Groundwater

Groundwater is important to the Great Lakes ecosystem because it provides a reservoir for storing water and slowly replenishing the lakes in the form of base flow in the tributaries. It is also a source of drinking water for many communities in the Great Lakes basin. Shallow groundwater also provides moisture to plants.

As water passes through subsurface areas, some substances are filtered out, but some materials in the soils become dissolved or suspended in the water. Salts and minerals in the soil and bedrock are the source of what is referred to as "hard" water, a common feature of well water in the lower Great Lakes basin.

Groundwater can also pick up materials of human origin that have been buried in dumps and landfill sites. Groundwater contamination problems can occur in both urban-industrial and agricultural areas. Protection and inspection of groundwater is essential to protect the quality of the entire water supply consumed by basin populations because the underground movement of water is believed to be a major pathway for the transport of pollution to the Great Lakes. Groundwater may discharge directly to the lakes or indirectly as base flow to the tributaries.

Lake levels

The Great Lakes are part of the global hydrological system. Prevailing westerly winds continuously carry moisture into the basin in air masses from other parts of the continent. At the same time, the basin loses moisture in departing air masses by evaporation and transpiration and through the outflow of the St. Lawrence River. Over time, the quantity lost equals what is gained, but lake levels can vary substantially over short-term, seasonal, and long-term periods.

Day-to-day changes are caused by winds that push water on shore (wind set-up). This is usually associated with a major lake storm, which may last for hours or days. Another extreme form of oscillation (seiche) occurs with rapid changes in winds and barometric pressure.

Annual or seasonal variations in water levels are based mainly on changes in precipitation and runoff to the Great Lakes. Generally, the lowest levels occur in winter when

much of the precipitation is locked up in ice and snow on land and dry winter air masses pass over the lakes, enhancing evaporation. Levels are highest in summer after the spring thaw when runoff increases.

The irregular long-term cycles correspond to long-term trends in precipitation and temperature, the causes of which have yet to be adequately explained. Highest levels occur during periods of abundant precipitation and lower temperatures that decrease evaporation. During periods of high lake levels, storms cause considerable flooding and shoreline erosion, which often result in property damage. Much of the damage is attributable to intensive shore development, which alters protective dunes and wetlands, removes stabilizing vegetation, and generally reduces the ability of the shoreline to withstand the damaging effects of wind and waves.

The International Joint Commission, the binational agency established under the Boundary Waters Treaty of 1909 between Canada and the USA, has the responsibility for regulation of flows on the St. Marys and the St. Lawrence Rivers. These channels have been altered by enlargement and placement of control works associated with deep-draft shipping. Agreements between the USA and Canada govern the flow through the control works in these connecting channels.

The water from Lake Michigan flows to Lake Huron through the Straits of Mackinac. These straits are deep and wide, resulting in Lakes Michigan and Huron standing at the same elevation. There are no artificial controls on the St. Clair and Detroit Rivers that could change the flow from the Michigan-Huron Lakes system into Lake Erie. The outflow of Lake Erie via the Niagara River is also uncontrolled, except for some diversion of water through the Welland Canal. A large percentage of the Niagara River flow is diverted through hydroelectric power plants at Niagara Falls, but this diversion has no effect on lake levels.

Studies of possible further regulation of flows and lake levels have concluded that natural fluctuation is huge compared with the influence of existing control works. Further regulation by engineering systems could not be justified in light of the cost and other impacts. Just two and a half centimeters of water on the surface of Lakes Michigan and Huron amounts to more than 36 billion cubic meters of water (about 1,260 billion cubic feet) (Figure 1).

Lake processes: stratification and turnover

The Great Lakes are not simply large containers of uniformly mixed water. They are, in fact, highly dynamic systems with complex processes and a variety of subsystems that change seasonally and on longer cycles.

The stratification or layering of water in the lakes is due to density changes caused by changes in temperature. The density of water increases as temperature decreases until it reaches its maximum density at about 4° Celsius. This causes thermal stratification or the tendency of deep lakes to form distinct layers in the summer months. Deep water

Great Lakes, North America, Figure 1 Wind set-up is a local rise in water caused by winds pushing water to one side of a lake.

is insulated from the sun and stays cool and more dense, forming a lower layer (the hypolimnion). Surface and nearshore waters are warmed by the sun, making them less dense so that they form a surface layer – the epilimnion. As the summer progresses, temperature differences increase between the layers. A thin middle layer, or thermocline, develops in which a rapid transition in temperature occurs.

The warm epilimnion supports most of the life in the lake. Algal production is greatest near the surface where the sun readily penetrates. The surface layer is also rich in oxygen, which is mixed into the water from the atmosphere. A second zone of high productivity exists just above the hypolimnion due to upward diffusion of nutrients. The hypolimnion is less productive because it receives less sunlight. In some areas, such as the central basin of Lake Erie, it may lack oxygen because of decomposition of organic matter.

In late fall, surface waters cool, become denser, and descend, displacing deep waters and causing a mixing or turnover of the entire lake. In winter, the temperature of the lower parts of the lake approaches 4°C (39°F) while surface waters are cooled to the freezing point and ice can form. As temperatures and densities of deep and shallow waters change with the warming of spring, another turnover may occur. However, in most cases, the lakes remain mixed throughout the winter.

The layering and turnover of water annually are important for water quality. Turnover is the main way in which oxygen-poor water in the deeper areas of the lakes can be mixed with surface water containing more dissolved oxygen. This prevents “anoxia”, or complete oxygen depletion, of the lower levels of most of the lakes. However, the process of stratification during the summer also tends to restrict dilution of pollutants from effluents and land runoff.

During the spring warming period, the rapidly warming nearshore waters are inhibited from moving to the open lake by a thermal bar, a sharp temperature gradient that prevents mixing until the sun warms the open lake surface waters or until the waters are mixed by

storms. Because the thermal bar holds pollutants nearshore, they are not dispersed to the open waters and can become more concentrated within the nearshore areas (Figure 2).

Living resources

As an ecosystem, the Great Lakes basin is a unit of nature in which living organisms and nonliving things interact adaptively. An ecosystem is fuelled by the sun, which provides energy in the form of light and heat. This energy warms the earth, the water, and the air, causing wind current evaporation and precipitation. The light energy of the sun is essential for the photosynthesis of green plants in water and on land. Plants grow when essential nutrients such as phosphorus and nitrogen are present with oxygen, inorganic carbon, and adequate water.

Plant material is consumed in the water by zooplankton, which graze the waters for algae, and on land by plant-eating animals (herbivores). Next in the chain of energy transfer through the ecosystem are organisms that feed on other animals (carnivores) and those that feed on both animals and plants (omnivores); together these levels of consumption constitute the food chain or web, a system of energy transfers through which an ecological community consisting of a complex of species is sustained. The population of each species is determined by a system of checks and balances based on factors such as the availability of food and the presence of predators, including disease organisms.

Every ecosystem also includes numerous processes to break down accumulated biomass plants, animals, and their wastes into the constituent materials and nutrients from which they originated. Decomposition involves microorganisms that are essential to the ecosystem because they recycle matter that can be used again.

Stable ecosystems are sustained by the interactions that cycle nutrients and energy in a balance between available resources and the life that depends on those resources. In ecosystems, including the Great Lakes basin, everything depends on everything else and nothing is ever really wasted.

Great Lakes, North America, Figure 2 Lake stratification (layering) and turnover. Heat from the sun and changing seasons cause water in large lakes to stratify or form layers. In winter, the ice cover stays at 0° C (32° F) and the water remains warmer below the ice than in the air above. Water is most dense at 4° C (39° F). In the spring turnover, warmer water rises as the surface heats up. In fall, surface waters cool, become denser, and descend as heat is lost from the surface. In summer, stratification is caused by a warming of surface waters, which form a distinct layer called the epilimnion. This is separated from the cooler and denser waters of the hypolimnion by the thermocline, a layer of rapid temperature transition. Turnover distributes oxygen annually throughout most of the lakes.

The ecosystem of the Great Lakes and the life supported within it have continuously altered with time. Through periods of climate change and glaciation, species moved in and out of the region; some perished and others pioneered under changed circumstances. None of the changes, however, has been as rapid as that which occurred with the arrival of European settlers.

When the first Europeans arrived in the basin nearly 400 years ago, it was a lush, thickly vegetated area. Vast timber stands consisting of oaks, maples, and other hardwoods dominated the southern areas. Only a very few small vestiges of the original forest remain today. Between the wooded areas were rich grasslands with growth as high as 2 or 3 m. In the north, coniferous forests occupied the shallow, sandy soils interspersed by bogs and other wetlands.

The forest and grasslands supported a wide variety of life, such as moose in the wetlands and coniferous woods, and deer in the grasslands and brush forests of the south. The many waterways and wetlands were home to beaver and muskrat which, with the fox, wolf, and other fur-bearing species, inhabited the mature forest lands. These were trapped and traded as commodities by the native people and the Europeans. Abundant bird populations thrived on the various terrains, some migrating to the south in winter, others making permanent homes in the basin.

It is estimated that there were as many as 180 species of fish indigenous to the Great Lakes. Those inhabiting the nearshore areas included smallmouth and largemouth bass, muskellunge, northern pike, and channel catfish. In the open water were lake herring, blue pike, lake whitefish, walleye, sauger, freshwater drum, lake trout, and white bass. Because of the differences in the characteristics of the lakes, the species composition varied for each of the Great Lakes. Warm, shallow Lake Erie was the most productive, while deep Superior was the least productive.

Changes in the species composition of the Great Lakes basin in the last 200 years have been the result of human activities. Many native fish species have been lost by overfishing, habitat destruction, or the arrival of exotic or non-indigenous species, such as the lamprey and the alewife. Pollution, especially in the form of nutrient loading and toxic contaminants, has placed additional stresses on fish populations. Other human-made stresses have altered reproductive conditions and habitats, causing some varieties to migrate or perish. Still other effects on lake life result from damming, canal building, and altering or polluting tributaries to the lakes in which spawning takes place and where distinct ecosystems once thrived and contributed to the larger basin ecosystem.

Recreation

Since early in the industrial age, the waterways, shorelines, and woodlands of the Great Lakes region have been attractions for leisure time activities. Many of the utilitarian activities that were so important in the early settlement and industrial development became recreational activities in later years. For example, boating, fishing, and canoeing were once commercial activities, but are now primarily leisure pursuits.

Recreation in the area became an important economic and social activity with the age of travel in the nineteenth century. A thriving pleasure boat industry based on the newly constructed canals developed, bringing people into the region in conjunction with rail and road travel. Niagara Falls attracted travelers from considerable distances and was one of the first stimulants to the growth of a leisure-related economy. Later, the reputation of the lower lakes region as the frontier of a pristine wilderness drew people seeking restful cures and miracle waters to the many spas and "clinics" that developed along the waterway.

In the twentieth century, more people had more free time. With industrial growth, greater personal disposable income, and shorter work weeks, people of all walks of life began to spend their leisure time beyond the city limits. Governments on both sides of the border acquired lands and began to develop an extensive system of parks, wilderness areas, and conservation areas in order to protect valuable local resources and to serve the needs of the population for recreation areas. Unfortunately, by the time the need for publicly accessible recreation lands had become apparent, much of the land in the basin, including virtually all the shoreline on the lower lakes, was in private hands. Today, about 80% of the US shoreline and 20% of the Canadian shore is privately owned and not accessible by the public.

The recreation industry includes production and sale of sports equipment and boats, marinas, resorts, restaurants, and related service industries that cater to a wide range of recreational activities. In some areas of the basin, recreation and tourism are becoming an increasingly important component of the economy in place of man manufacturing. The Great Lakes basin provides a wide range of recreational opportunities, ranging from pristine wilderness activities in national parks such as Isle Royale and Pukaskwa to intensive urban waterfront beaches in major urban areas.

The increasingly intensive recreational development of the Great Lakes has had mixed impacts. Some recreational activities cause environmental damage. Extensive development of cottage areas, summer home sites, beaches, and marinas has resulted in loss of wetland, dune, and forest areas. Shoreline alteration by developers and individual property owners has caused changes in the shoreline erosion and deposition process, often to the detriment of important beach and wetland systems that depend upon these processes. The development of areas susceptible to flooding and erosion has caused considerable public reaction. There is pressure to manage lake levels to prevent changes that are part of natural weather patterns and processes. Pollution from recreational sites and boats has also caused water-quality degradation.

Recreational uses are a threat to the quality of the Great Lakes ecosystem, but also provide a basis for protecting quality by attracting and involving people who recognize that protection of the ecosystem is essential to sustain the recreation that they value. People who use the water for its fun and beauty can become a potent force in the protection of the ecosystem. Naturalists, anglers, and cottagers were among the first to bring environmental issues to the attention of the public and call for the cleanup of the lakes in the 1950s and 1960s when eutrophication threatened favored fishing, bathing, and wildlife sites. Today, more people than ever use and value the lakes for recreational purposes.

Recent years have seen a major resurgence in recreational fishing as the walleye fisheries recover and the

new salmon fisheries develop. Lake Ontario now sports a very important salmon and trout recreational fishery. The water-quality recovery in Lake Erie has been complemented by record walleye reproduction in recent years. In many areas – Buffalo, Cleveland, Chicago, and Toronto particularly – there have been urban renewal movements with the lake front as a primary focus. Developing public access to the water is a key element of these renewal projects.

Nutrients

Temperatures of many tributaries have been increased by removal of vegetative shade cover and some by thermal pollution. But, more importantly, the amount of nutrients and organic material entering the lakes has increased with intensified urbanization and agriculture. Nutrient loading increased with the advent of phosphate detergents and inorganic fertilizers. Although controlled in most jurisdictions bordering the Great Lakes, phosphates in detergents continue to be a problem where they are not regulated.

Increased nutrients in the lakes stimulate the growth of green plants, including algae. The amount of plant growth increases rapidly in the same way that applying lawn fertilizers – nitrogen, phosphorus, and potassium – results in rapid, green growth. In the aquatic system, the increased plant life eventually dies, settles to the bottom, and decomposes. During decomposition, the organisms that break down the plants use up oxygen dissolved in the water, near the bottom. With more growth, there is more material to be decomposed and more consumption of oxygen. Under normal conditions, when nutrient loadings are low, dissolved oxygen levels are maintained by the diffusion of oxygen into water, mixing by currents and wave action, and by the oxygen production of photosynthesizing plants.

The Boundary Waters Treaty of 1909

In 1905, the International Waterways Commission was created to advise the governments of both countries about levels and flows in the Great Lakes, especially in relation to the generation of electricity by hydropower.

Its limited advisory powers proved inadequate for problems related to pollution and environmental damage. One of its first recommendations was for a stronger institution with the authority for study of broader boundary water issues and the power to make binding decisions.

The Boundary Waters Treaty was signed in 1909 and provided for the creation of the International Joint Commission (IJC). The IJC has the authority to resolve disputes over the use of water resources that cross the international boundary. Most of its efforts for the Great Lakes have been devoted to carrying out studies requested by the governments and advising the governments about problems.

In 1912, water pollution was one of the first problems referred to the IJC for study. In 1919, after several years

of study, the IJC concluded that serious water quality problems required a new treaty to control pollution. However, no agreement was reached.

Additional studies in the 1940s led to new concerns by the IJC. The Commission recommended that water quality objectives be established for the Great Lakes and that technical advisory boards be created to provide continuous monitoring and surveillance of water quality.

Public and scientific concern about pollution of the lakes grew as accelerated eutrophication became more obvious through the 1950s. In 1984, the IJC began a new reference study on pollution in the lower Great Lakes. The report on this study in 1970 placed the principal blame for eutrophication on excessive phosphorus.

The study proposed basin-wide efforts to reduce phosphorus loadings from all sources. It was recognized that reduction of phosphorus depended on control of local sources. Uniform effluent limits were urged for all industries and municipal sewage treatment systems in the basin. Research suggested that land runoff could also be an important source of nutrients and other pollutants into the lakes. The result of the reference study was the signing of the first Great Lakes Water Quality Agreement in 1972.

GREAT SALT LAKE

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Description

The origin of the Great Salt Lake in the USA can be traced back to ancient Lake Bonneville which covered much of western Utah and small parts of Idaho and Nevada during the Pleistocene Epoch (known as the Great Ice Age) between 23,000 and 12,000 years ago in the warmer and drier period that followed the Ice Age. Lake Bonneville receded and the Great Salt Lake as it is today is a descendant of that ancient lake (Fig. 1).

The combination of size and salt content makes the Great Salt Lake unique. Since the lake has no outlet, all the minerals brought in from the nearby mountains remain in the lake. It is estimated that more than two million tons of minerals are added to the lake each year and the lake has a dissolved mineral content of some four to five billion tons, although these figures vary as the salinity of the lake varies. The lake is one of the saltiest bodies of water in the world, and only the Dead Sea between Israel and Jordan has a higher salt content. The percentage of salt in the lake varies depending on the water level, and percentages of salt as great as 27% have been found in the lake. The lake level has been monitored since 1847. The inflow to the lake is mainly from the streams Bear, Weber, and Jordan; precipitation; and groundwater. The lake loses water by evaporation from the surface. So long as inflow exceeds evaporation, the lake level will rise, and because the lake is mainly closed, a small change in depth results in a large change in surface area, and, therefore, the position of the shoreline is extremely variable. A prolonged period of wet weather in 1982–1986 caused the lake to flood parts of Salt Lake City and threatened the transcontinental railroad and highways along the shores.

There are eight named islands in the lake that have never been totally submerged. All have been connected to the mainland by exposed shoals during periods of low water. They range in size from Antelope Island with an area of 93 million squaremeters to Hat Island with an area of 90,000 m².

The Great Salt Lake was only discovered in the winter of 1824–1825 by Jim Bridger, but the first exploration was conducted by John C. Freeman and his party in 1843. The railroad was commenced across the lake in 1902 when a 12-mile-long trestle of 28,000 wooden pilings crossed Great Salt Lake and made the railroad an integral part of the lake. After World War II, a causeway was built to replace the trestle across the lake.

Great Salt Lake, Figure 1 Landsat 5 image of Great Salt Lake, September 2010 (Courtesy of the USGS).

The Great Salt Lake has a variable surface area of 5,950 km² and an average capacity of 1.6 million. The altitude of the lake is 1,250 m above mean sea level and is about 110 km long and about 50 km wide at the elevation of 1,250 m. The depth of the lake varies with surface area but has an average of about 4 m.

H

HAZARDS

Simon Dobby
Health and Safety Emerging Planning Unit, Metropolitan
Borough Council, Barnsley, UK

General concepts

The concept of hazard identification and management is widely acknowledged in many fields, including environmental and health and safety management, as a tool for preventing or minimizing harm. A hazard may be defined as a situation with the potential to cause harm. Three main elements are contained within the hazard definition: *situation*, *harm*, and *potential*. Situation refers to what could occur (e.g., heavy metals may enter surface waters). Harm may be in terms of detriment, injury, or ill health to people; damage to the environment; or a combination of these, for example, contamination of lake sediments. However, it is not sufficient to identify only what could occur if hazards are to be managed. The possible likelihood and extent of the potential effects need to be determined in order that action can be taken.

This introduces the concept of risk and the assessment and management of risk. The risk from a hazardous situation is a combination of the likelihood that it will cause harm and the magnitude of the harm that could be caused. The risk concept therefore moves from a pure identification of what harm could occur to a determination of what harm is likely to occur and what may cause the most harm (i.e., the likelihood and consequences of a hazardous event occurring (BSI, 2007)). Once determined, risks can then be assessed to decide whether they are acceptable. Risk assessment informs decisions on how to manage risks and is therefore the overall process of determining the likelihood and consequences of a hazardous situation occurring, estimating

the level of the risk, and deciding upon how to manage the risk based on the measures taken and which could be taken (BSI, 2007). The link between hazard and risk must be understood if hazardous situations and hence risks are to be managed.

There is a plethora of techniques for risk assessment ranging from simple risk screening (e.g., where the risk is undeniably negligible) to complex methods of assigning data to risks. Two main methods of risk assessment exist: quantitative and qualitative. Quantitative risk assessment is an objective approach to the assessment of risk. Quantitative risk assessment techniques are generally mathematics/engineering based, complex, and aim to quantify risk expressed in units such as incidents of a certain severity per annum (Guy, 2001). Conversely, qualitative risk assessment is a subjective approach to risk assessment that considers that the perception of risk is different to different people depending on their experiences (Guy, 2001). Qualitative risk assessment may encompass a simple semiquantification of risk such as assigning defined categorizations of low, medium, and high as both measures of the severity of consequences and the likelihood of occurrence. However, these labels are generally assigned based on the perception of the assessors rather than specific calculation. Despite their inherent differences, generally, risk assessments follow the same underlying process (BSI, 2007; Pollard and Guy, 2001):

1. Identification of hazards
2. Determination of the risks associated with the hazards by:
 - (a) Identification of the potential consequences of the hazard
 - (b) Determining the potential severity of harm
 - (c) Assigning a value or judgment (be it quantitative or qualitative) to the likelihood of the potential hazard being realized

3. Preparation of a relative hierarchy of risks by relating them to other risks
4. Deciding if the risks are acceptable by reference to standard approaches to measuring tolerability and/or taking into account economic, social, technological, or management issues
5. Preparation and implementation of a risk control plan as necessary based on the prepared hierarchy and acceptability of the risks
6. Reviewing and monitoring the risk assessment process and risk control plan as necessary

Risk management is the holistic process of hazard identification, risk assessment, and risk control, with the greatest risks (be they determined objectively or subjectively) being the priority with regard to action to manage those risks. Therefore, there is an obvious need for consideration of both quantitative and qualitative risk assessment in order to manage hazards and risks particularly where public perception is inherent to the methods adopted for risk management (Guy, 2001). However, it is essential to consider that while risk assessment can provide useful information, it cannot, by its nature, fully take account of the uncertainties of people. Risk management strategies for lakes and reservoirs may require that hazards and risks are assessed and considered in terms of the entire body of water and its environment and that there is coordination between those placing demands of the water (UNEP, 1994). In addition, the management of lakes and reservoirs may need to encompass the concept of sustainability by meeting the needs of the present without compromising the future.

Hazards associated with lakes and reservoirs

Lakes and reservoirs are associated with hazards. The hazards may be *to* (e.g., pollution or silting) or *from* (e.g., working on or near water) the lake or reservoir. Hazards related to lakes and reservoirs include: water quality; pollution; silting; pathogens; drought; land use; flooding; habitat destruction; security; public access; working over, on, or near water; habitat destruction; and reservoir safety hazards.

Water quality

The quality of freshwater is vitally important for many ecosystems. Not only is water used to fulfill the basic human needs of drinking, cooking, and washing but for a plethora of other domestic, commercial, agricultural, industrial, and recreational activities. In addition, water provides a biologically diverse habitat for wildlife. Despite the demands placed upon it, the water found in rivers and freshwater lakes accounts for around a quarter of one percent of all the freshwater on the planet (UNEP, 1994). Therefore, water quality and its management is a balance between the different uses of water. Water quality hazards arise when water quality is adversely affected, commonly by human activity causing pollution in some form or another. The management of

water quality to minimize risk needs to incorporate measures to prevent and mitigate hazards through technological, managerial, social, and legislative actions.

Pollution

Pollution may be variously defined; however, it is generally the entry of substances or energies into the environment that are potentially harmful to ecological systems, (NSCA, 1992). It is inextricably linked to water quality and is arguably its greatest threat with many human activities either polluting or having the potential to pollute water (including recreational activities). Pollution may be caused directly or indirectly, accidentally or deliberately, slowly or quickly and can arise from a point source, such as commercial or industrial discharges, or may be more dispersed and diffuse, such as agricultural runoff or urban drainage (Environment Agency, 2004). However, whatever its method of delivery, pollution can have wide ranging effects in the short, medium, and long term. Pollution from point sources is relatively simple to control by technological, managerial, and legal processes. However, because of the nature of diffuse pollution that arises from hundreds or thousands of sources, it is more difficult to control (CIWEM, 2003). Pollution may enter lakes and reservoirs by direct entry to surface water, entry to groundwater, runoff from the land, or deposition from the atmosphere.

A general list of pollutants entering the water cycle includes: chemicals (organic and inorganic), radioactivity, heat, oxygen-consuming matter, inert solids, wastes (solid and liquid), sewage, nutrients, and microorganisms. All these pollutants have potentially adverse effects on water quality depending upon their exact nature in terms of chemical, biological, and physical properties; quantity; and concentration. The consequences of pollution include: toxic effects on flora and fauna, eutrophication, silting, increase in pathogens, increased water treatment costs, adverse visual effects, and loss of habitat.

Silting

Silting refers to the deposition of sediments. Its causes are varied and include soil erosion and a decrease in the velocity of water in a lake or reservoir. The sediment carried into a body of water may contain nutrients or contaminants that have adverse effects on water quality. In addition, silting may lead to decreased water storage capacity and loss of wildlife habitat. Measures to reduce silting include the proactive minimization of ground and surface erosion, particularly in catchment areas, and reduction of pollution and reactive dredging of silted areas.

Pathogens

Pathogens are disease-causing organisms and include bacteria, viruses, and parasitic worms (helminth). Pathogens may enter surface water via contaminated biological wastes, including human and animal fecal wastes, and emanate from both distinct and diffuse sources. Large

numbers of pathogens may be found in lakes particularly after rainfall when surface runoff carries contaminated material from the land into the water (Severn Trent Water, 2004). Diseases caused by pathogens are wide ranging and include infectious and parasitic diseases, which vary worldwide and include typhoid, cholera, and bilharzia in areas of less-developed water treatment. Risk controls for pathogens include prevention of water pollution by fecal matter by suitable wastewater treatment and effective drinking water treatment.

Drought

Drought and flooding are arguably opposites with both arising from relatively extreme fluctuations in water level due to natural or human causes. When the water level in a lake decreases either by overabstraction, lack of rainfall, or diversion of tributary rivers, this results in a decrease in lake area and volume. The potential effects of this include: temporary eutrophication, concentration of minerals in the water, damage to industries that depend on lake resources (such as for fishing or dispersion of pollution), and damage of ecosystems (UNEP, 1994). While there is no method to prevent periods of low rainfall, overabstraction may be minimized to reduce risks and other measures adopted to lessen the impact of drought such as prevention of silting and pollution and maintenance of habitats.

Flooding

The area and volume of lakes and reservoirs may increase with heavy precipitation and surface runoff, whether it is caused by predictable wet periods or thaw, or less-encountered events such as atypical rainfall. Increases to the flow into the lake or reservoir may cause flooding to the body of water itself and flooding both up- and downstream of the lake or reservoir as it reaches its natural or designed capacity. The effects of flooding include habitat damage, increased risk to the safety of people, and the damage of property. However, it must always be borne in mind that flooding in the case of natural lakes may be a normal process that brings benefits such as the conditioning and fertilization of arable land.

Risk control with regard to flooding (and drought) is concerned with the management of the effects of the environment on ecosystems and people rather than the effects of people on the environment and ecosystems (as is often the case). Risk controls for the management of flooding include: precipitation prediction; flood modeling; the development of appropriate warning and informing and emergency arrangements; the development of physical flood prevention or minimization measures such as control structures, protective walls, and water storage areas, making premises resistant to flooding; and the development of recovery arrangements.

Land use

The expansion of natural lakes and the creation or expansion of reservoirs inevitably uses land. In the case of the

latter, the perceived benefits of the land use may vary greatly. Large bodies of water cannot only create habitats for wildlife and amenities for people but also damage existing features of the natural or human landscape. Measures can be taken to minimize the expansion of natural lakes if they are likely to impinge upon habitats or resources and include increasing the outflow from the lake. The effects of the development of existing or proposed reservoirs can be minimized by environmental impact assessment, which aims to provide a balanced assessment of the need for a development that describes the proposals, provides the information used to evaluate the environmental effects, and gives details of the environmental effects and the measures taken to reduce or avoid them.

Security

People may wish to access lakes and reservoirs for leisure activities; however, they may also wish to gain access (including access to associated infrastructures) for nefarious activities. Risks associated with nefarious activities include pollution of the water, poaching, and access to buildings and infrastructure controls. General security measures that can be adopted to minimize risks include: use of closed-circuit-television (CCTV) systems and security fences; locking of access gates, doors, and inspection and access covers; adoption of security patrols and intruder detection systems; and covering of small reservoirs in populated areas.

Public access

Open water is integral to the leisure activities of many people. The main hazard associated with public access to lakes and reservoirs is drowning following accidental or deliberate entry into the water (Water UK, 1999). In the United Kingdom during 2001, drowning in lakes and reservoirs accounted for 12% of total drowning (RoSPA, 2003). Leisure activities associated with lakes and reservoirs include: walking, swimming, diving, water sports, motorized water sports, angling, and (weather conditions allowing) ice-skating. In addition to the effects on people, these activities may have effects on local flora and fauna, water quality, and the existence of pollutants such as oil and general waste. Some of these activities need to be segregated or prohibited to prevent damage to the environment and accidents to people (e.g., diving and other water sport activities should be segregated due to the risk of injury, diving may not be acceptable in sensitive nature conservation areas, pollution from motorboats may damage local ecosystems). Public safety in periods of extremes of weather (hot weather leading to bathing or easy access to infrastructure in periods of drought and cold weather leading to ice formation) is a particular consideration.

The risks associated with public access to lakes and reservoirs may be reduced by measures including: removal of reservoirs (particularly reservoirs in populated

areas); general security measures; barriers (particularly at high-risk areas); warning notices; prohibition of water activities, including water sports; provision of appropriate access routes and emergency equipment; fencing; inspection and maintenance of control measures; and the provision of information, instruction, and training to higher-risk groups (such as children) (Water UK, 1999). In addition, ice breaking may be carried out around the edges of frozen water to dissuade people from walking on it; however, this poses a risk to those undertaking the ice breaking (RoSPA, 2003).

Working over, on, or near water

Working over, on, or near water presents a danger that people may slip, trip, or fall into water or be swept off their feet by water leading to injuries and the risk of drowning. As with all work activities, working over, on, or near water needs to be carried out in a safe and healthy manner adopting appropriate control measures to minimize risks and mitigate the effects of any incident. General controls that may need to be adopted when work is carried out over, on, or near water include provision of appropriate platforms and gangways; safety nets and safety harnesses; illumination; first aid equipment; personal protective equipment and clothing, including personal buoyancy equipment; suitable means of access to and egress from the location; and suitable rescue equipment and procedures. In addition, it may be necessary to ensure work sites are suitably tidy and carefully consider the current and anticipated weather conditions (Construction Health and Safety, 2002).

Habitat destruction

Many of the hazards described thus far can have a detrimental effect on habitats. Lakes and reservoirs are a large and diverse habitat for flora and fauna. Pollution; silting; pathogens; drought; land use; flooding; security; public access; and working over, on, or near water can act to disrupt or even devastate habitats. Therefore, habitat destruction may arguably be a side effect of another hazard or combination of hazards.

Reservoir safety hazards

In addition to the hazards outlined above, reservoirs may present further hazards. Hazards associated with reservoirs are primarily associated with the structural integrity of the dam and associated infrastructure due to leakage, soil movement/slippage, water seepage, spoiling of pointing between stone blocks, and increased or unusual vegetation growth associated with the dam or embankment. Additional hazards include blockage of spillways, silting of overflows, inoperable sluice controls, burrows into soil embankments, and intrusion of vegetation into structures. With regard to occupational hazards other than those previously discussed, issues to consider include working at height and working with electricity generation and distribution infrastructures.

HEALTH ASPECTS OF LAKES AND RESERVOIRS

David Bradley
 Department of Zoology, University of Oxford, Oxford, UK

Definition

Health aspects of Lakes and Reservoirs can refer to all the ways in which the creation, existence, and use of reservoirs and other lakes can influence human health. This entry deals with the relation of lakes and reservoirs to communicable diseases chiefly, as chemical and physical hazards are largely separate while very indirect effects through changes in income or agricultural innovations

made possible by irrigation would spread the material too thinly, although they do have substantial effects.

A *reservoir* is a man-made water impoundment where the water is used in a controlled way for specific human ends. Most reservoirs are created by placing a *dam* across a stream. In some countries, and especially for small impoundments, the term *dam* is applied to the reservoir as well as the retaining wall. In South Asia the term *tank* is also used.

By *communicable diseases* we mean *infectious diseases*, which can spread directly, or through water, from the patient to other people, plus *transmissible diseases* that have an insect vector or a water snail intermediate host between the stages in the human host.

Introduction

Lakes and reservoirs have a great influence on human health, both directly and indirectly, often for the good, but also frequently leading to illness and sometimes death. Communicable, noncommunicable, and traumatic harm may all be related to lakes, whether natural or man-made. The latter are of particular importance, since by varying the way in which reservoirs are made and operated it is possible to prevent or at any rate diminish many adverse effects on health.

The unhealthy effects of reservoirs are often primarily due to the uses to which the stored water is put. In particular, the use of water for irrigated agriculture is associated with infectious and parasitic diseases, especially in the tropics. In an irrigation scheme, large populations of workers are closely and repeatedly exposed to water contact. Diseases which occurred at the margin of reservoirs and lakes may be widespread across the whole of an irrigation scheme.

The majority of all the health hazards related to communicable disease around reservoirs and lakes are due to events taking place near the edge of the lake or in shallow areas. Reservoirs in general differ from most lakes in that they have a larger annual fluctuation of depth as the water level rises and falls under human control and in relation to various needs. Usually, the consequence is that the flow of water below the dam is more evenly distributed through the year than is the case with a natural lake overflowing. Health impacts of man-made lakes are due to both the process by which they are created and the ways in which they are subsequently operated. These are best considered separately, but it has to be remembered that resources for disease control and particularly for health care are much more readily available in the construction phase than thereafter, and the construction phase provides an opportunity to create a sound health care infrastructure which will persist for many years following the filling of the reservoir.

It is important when planning a reservoir to consider the whole catchment and the effects that its construction and operation will have upon the water throughout the catchment. Often the indirect effects of reservoir construction will be felt for a long way downstream. Where reservoir

creation leads to upstream flooding of inhabited areas, adequate provision is critical for the displaced population. Historically, those people have fared very badly out of the creation of man-made lakes. Enough is known from earlier experience to avoid many of these problems, but usually there are still inadequate resources provided at the planning stage and consequently this difficult and complex operation is very detrimental to the displaced people.

Whenever a man-made lake is planned, it is essential at an early stage in the planning process to undertake a health opportunity assessment on a scale appropriate to the size of the project. Historically, such matters were not considered until relatively recently. Then the concept of an environmental impact assessment of water resources development was introduced and, mainly from evidence of schistosomiasis spread, this was developed into a health impact assessment. More recently it has been realized that not only should reservoir creation not lead to an increase in the local endemic diseases nor to outbreaks of epidemics, but also it provides an admirable opportunity to improve the health and health care facilities for the population who will be living around the lake.

This entry will focus particularly upon communicable diseases. In relation to lakes and reservoirs it is possible to classify communicable diseases by the biological nature of the causative agent, but it is more helpful to those outside the health sector to consider the different modes of transmission, because these point to the environmental modifications which can reduce transmission and which are usually the responsibility of those outside the health sector.

Water-related disease transmission

There are four main categories of transmission of water-related communicable diseases.

1. *Truly Waterborne Diseases*. These are infections where the causative organism is transmitted from one person to another by the water route. These are the concerns particularly of those providing drinking water for domestic use and where the aim will be to reduce the chance of disease being conveyed to people who drink the water. Disease transmission by this route requires both pollution of the water by a person or an infected animal and subsequent survival of the organism in the water with or without multiplication, and then for people to ingest the organisms. The classical diseases in this category are cholera and typhoid and the causes of watery diarrheas, and also *Shigella* or bacterial dysentery. As with most infections involving water bodies, transmission will largely take place at the water's edge, where pollution by excreta may occur and people collect domestic water and bathe, or near to it in shallow water offshore or wetlands near to the shore. The smaller the water body, the greater is the risk. Therefore, the risk of ingesting enough organisms to transmit the disease is relatively low in large lakes, especially

away from the shore, because of the huge dilutions involved. By contrast, small pools and ponds can very easily become polluted and if used as a source of drinking water may well pass on these organisms. Although both natural lakes and many reservoirs are used deliberately as a source of drinking water for substantial communities, the water will usually be treated before it reaches the distribution system of pipes and taps. Space does not permit an extensive discussion of water treatment. Most commonly, when pollution occurs and leads to large outbreaks of disease it is because of contamination close to or within the transmission system from the lake to the users and particularly when the water treatment works is not functioning satisfactorily. Where water is collected by individuals from poorer households around the lake there will be a risk, usually less for a large water body.

2. *Water Washed Transmission of Diseases.* It has been found that, for many of the diseases once thought primarily to be transmitted through drinking water, the availability of adequate water for personal cleanliness, accompanied by suitable hygiene behavior, such as the use of soap for hand-washing after defecation, can greatly reduce the incidence and severity of diarrheal diseases. It is easier for those living close to the shore of a lake or reservoir, even if they are having to use untreated water from the margin, to obtain adequate water for washing and personal use, and so to this extent the hazard of diarrheal disease and of skin infections and the blinding eye disease, trachoma, is reduced for such people. By contrast, in other respects, living very close to water may increase the risk of vector-borne diseases. It must be remembered that where villages are sited away from large water bodies it is critical to provide adequate water right to the village, preferably taken from some distance away from the shore of the lake, even if it is not possible to treat the water properly for domestic use.
3. A group of infections called *Water-Based Diseases* are of great importance in relation to lakes, and even more so in relation to reservoirs in many parts of the tropics and subtropics. These diseases are where the causative organism has a life cycle, part of which is spent inside people and part in organisms that live in the water. The most important of these are the various trematode or flatworm infections (sometimes called fluke infections), which have stages in water snails, and in particular the several forms of schistosomiasis, described below; but there are also rarer infections, which pass from people to snails, and then from the snails into what are called second intermediate hosts, usually fish, and people become infected by eating the fish inadequately cooked.
4. Water bodies act as breeding sites for *Water-Related Insect Vectors of Disease* in warm-climate countries. The mosquitoes predominate as vectors and the key diseases transmitted are arbovirus fevers and malaria (see below). The majority of mosquitoes breed

preferentially in small water bodies and in shallow wetlands such as rice fields, but the edges of lakes and still more of reservoirs provide breeding habitats for several important vectors. These may be in fringing vegetation or in puddles left by falling water levels of reservoirs. A specialized group of floodwater mosquitoes have resilient eggs which can survive in sand near the high watermark for long periods, rapidly hatching when the next inundation occurs, sometimes several years later. These floodwater mosquitoes carry certain arboviruses in particular.

Other insect vectors of human disease associated with reservoirs are *Simulium* vectors of the worms which cause river blindness or onchocerciasis. They are small biting flies whose larvae, needing highly aerated water as a habitat, especially occur on dam spillways and in torrential feeder streams for the reservoir. The tsetse flies, *Glossina*, that transmit sleeping sickness (trypanosomiasis) in Africa include some species that bite in tree-shaded fringes of lakes, most notably Lake Victoria.

Some diseases that fall into categories 3 and 4 are of particular relevance and are considered in more detail.

Diseases particularly transmitted in lakes and reservoirs

Schistosomiasis

Schistosomiasis is the dominant problem associated particularly with man-made lakes, although transmission takes place also in natural lakes in parts of Africa, Latin America, and southeast Asia in particular. All the human schistosomes have a basically similar life cycle. The parasites live in the blood vessels of their human host, and lay eggs which escape in the excreta, whether urine or feces depends upon the species of *Schistosoma* involved. If the excreta pollute the water the eggs of the schistosome hatch out to set free a microscopic larva, or miracidium, which swims about for some hours. If it encounters a suitable species of water snail, this larva will penetrate the tissues of the snail and infect it. Over the next month, the parasite will develop within the body of the snail, gradually destroying many of its internal organs, and after some weeks the larval schistosomes will emerge and swim about in the water. This will happen daily for the rest of the snail's life. If people are wading in the water, the schistosome larva, or cercaria as it is called, will rapidly attach to their skin and then bore through the skin into the blood vessels beneath. The cercariae will be swept to the lungs and subsequently other organs of the body, where they will undergo development. The sexes of *Schistosoma* worms are separate, and when they mature they migrate to the blood vessels of the bladder and intestinal walls, pair, and the female will begin laying eggs on a substantial scale. *Schistosoma* worms are very long-lived and it has been found that people who have become infected and then moved away from the chance of further infection may go on passing eggs in substantial numbers for decades. Many of the *Schistosoma* eggs do not

successfully escape from the host and they are the cause of much damage to the tissues of the person who is infected.

There are five main species of *Schistosoma* that infect people. *Schistosoma haematobium* lives in the blood vessels around the bladder of the infected person, and the eggs that are laid by the worm gradually find their way from the blood vessel through into the lumen of the bladder, so that they escape when the infected person urinates. Many eggs accumulate and die in the tissues of the ureters and bladder. Fibrosis and inflammation around the eggs leads to damage to the bladder wall and ureters and also encourages the formation of urinary stones or calculi. Damage may occur to the kidneys as a result of obstruction to the flow of urine. In very heavy infections, as used to be observed particularly in Egypt, cancer of the bladder is a major complication. *S. haematobium* is found throughout much of Africa and in parts of Western Asia. It is transmitted by aquatic snails of the genus *Bulinus* with a rather low spire, some of which can aestivate in the mud of desiccated pools during the dry season.

S. mansoni has a more restricted distribution in tropical Africa and the Nile basin, also the Arabian Peninsula, South America, and the Caribbean. The aquatic intermediate host snails are flat spiral snails of the genus *Biomphalaria*. The adult worms live in the blood vessels around the large intestine, so that the eggs they lay pass through its wall and are shed in the person's feces. The pathological effects are mainly due to many eggs that do not escape being carried in the portal vein to the liver, where they get impacted and an inflammatory reaction occurs around them. Eventually the eggs are destroyed, but in some people, the fibrous tissue left behind by vast numbers of eggs eventually causes extensive and potentially fatal liver fibrosis. *Schistosoma intercalatum* in West Central Africa behaves similarly to *Schistosoma mansoni*, though its eggs resemble those of *Schistosoma haematobium*. *Schistosoma japonicum* of East Asia and parts of SE Asia has a similar pathology to *S. mansoni*, but far more eggs are laid by each female and the chance of severe disease is much greater in *S. japonicum* infections. *Schistosoma mekongi* is very similar and occurs, as its name suggests, chiefly in the Mekong Valley. *S. japonicum* has a small amphibious snail of the genus *Oncomelania* as the intermediate host, whereas *S. mekongi* has an aquatic snail, *Tricula*.

Schistosomes are par excellence the parasites associated with water resource developments. Much is known about the biology of the varied local species of intermediate host snails, so that the risks of schistosomiasis can be predicted approximately at the planning stage, but not with precision. Thus, when the Volta (Akosombo) dam in Ghana was being constructed, a schistosomiasis problem was foreseen for the lake, but the species of snail and the type of schistosomiasis were unexpected: there was a large *S. haematobium* problem imported by migrant fishermen and spread by dense *Bulinus* populations. However, the later downstream dam at Kpong, which is kept at

a relatively constant water level perennially, supported snails transmitting both schistosome species. Jobin (1999) has pointed out that this is replicated in some other pairs of dams in Africa, reasoning that *Bulinus* thrives in the upper reservoir in spite of large annual fluctuations in the water level whereas *Biomphalaria* is also present in the lower reservoir which is kept at a relatively constant level. A few species of *Biomphalaria* can live in deep water and have been responsible for offshore schistosomiasis transmission.

A biologically related problem of temperate climate reservoirs involves those schistosomes with birds as their definitive hosts. Sometimes very large numbers of water snails become infected with their developmental stages and huge numbers of cercariae are shed. These are able to penetrate human skin but not to survive further, and there is an inflammatory response to the dead cercariae. This leads to outbreaks of a rash called "schistosome dermatitis" among lake bathers in the late summer in the USA, UK, and many other countries.

Malaria

In the case of malaria, the most important vector-borne disease globally, the consequences of water resource development depend heavily on the baseline level of malaria transmission and the type of water development. The infection is transmitted by female mosquitoes of the genus *Anopheles*, which become infected by feeding on the blood of people with malaria. The parasites develop in the mosquito, migrate to its salivary glands after 1–2 weeks, and then are inoculated into other people when the mosquito feeds again. The parasites then multiply repeatedly, first in the liver and then in the human blood cells, the latter on a 2–3-day cycle so that the patient gets an intermittent fever which worsens as parasite numbers increase in the blood. In nonimmune people, death may follow from disturbance to the brain (cerebral malaria) in children and adults and from anemia in infants if they are suffering from *falciparum* malaria (of the four species of malaria that commonly infect man, this causes by far the most severe illness and is especially prevalent in Africa). At low levels of transmission prior to the development, as in many parts of India, the creation of a reservoir, and particularly one that feeds an irrigation scheme, has historically been followed by epidemic malaria. By contrast, in parts of West Africa with very heavy transmission of malaria already taking place, creation of a reservoir or irrigation scheme may greatly increase the abundance of vector mosquitoes but with little or no increase in clinical malaria. This is because the existing level of transmission is so high that children are already infected with malaria from early infancy, and acquired human immunity regulates the levels of disease observed. Indeed, in some parts of Africa the creation of irrigated rice agriculture appears to decrease the malaria level somewhat; this is sometimes known as the "paradox of the paddies" and it is not yet fully understood.

Importance of disease due to large dams

The infectious and communicable disease burden due to water resource development has been assessed for several key vector-borne diseases, primarily in relation to the larger dams and reservoirs. Malaria and schistosomiasis are greatly affected by surface water storage.

The effect will vary greatly with the baseline endemicity and local vector species, so that, for example, four times larger a percentage of schistosomiasis incidence can be ascribed to dams in South East Asia than in Africa, although the actual number of people involved is far greater in Africa south of the Sahara. Meticulous calculations have been made by Kaiser, Utzinger, and colleagues in a series of systematic reviews of the key vector-borne diseases, and the results are summarized in Table 1. Globally it appears that some 42 million people are at risk of schistosomiasis from big water storage dams, of whom 10 million are infected (Steinmann et al., 2006), while 18 million are at risk of malaria as a consequence of water storage in large dams (Keiser et al., 2005).

Environmental measures of disease control

There is sufficient knowledge to propose interventions against many pathogens and vectors but, as with most control by environmental means, interventions need to be appropriate for the local organisms and human activities and also to be maintained scrupulously, which is operationally not easy. Engineered environmental changes often need to be accompanied by changes in human behavior. Structural changes to prevent disease transmission are usually called environmental modification, while recurrent management issues such as clearing vegetation, sluicing, and regulating salinity are called environmental manipulation.

The water level of many lakes and all reservoirs tends to vary on an annual cycle. The extent of this variation, along with the slope of the shoreline and the rate of drawdown, will substantially affect populations of vector insects and intermediate host snails.

Because the vast majority of the health effects of lakes and reservoirs are determined by events close to the edge of the impoundment, its nature is of great importance.

A steep shore that is unsuitable for human waterside activities, lacks vegetation and descends sharply below the water level will be most conducive to health. Where the shoreline is gently sloping and supports emergent and floating vegetation it provides a habitat for snails and mosquito larvae, especially where wave action is reduced. In Africa, fringing trees may need clearing or their lower branches removing to deter tsetse flies from biting. Human settlements should be sited away from the shore (preferably over 2 km) but water piped to them and sanitation facilities provided. In tropical areas, the aim will be to minimize contact between the people and the reservoir edges, such as by constructing jetties and cleared landing places, although, particularly among fishing communities, substantial water contact may be inevitable. Where schistosomiasis is endemic, infection may well occur, although the worm burden and so the chance of serious disease may be greatly reduced by these environmental and behavioral measures. There is now satisfactory chemotherapy available and a regular cycle, perhaps annually, of testing and treatment for schistosomiasis may be needed. Although molluscicides are available, their sustained use in lakes and reservoirs (apart from small pools and night storage ponds for irrigation) is impracticable.

Deliberate variation of the water level for disease control has been used for some reservoirs to control schistosomiasis and malaria. In the pre-1939 "golden age" of environmental management for vector control, just prior to the introduction of residual insecticides, particular attention was paid to varying the water level of reservoirs in a controlled way, especially in the USA, deriving from the experience of the Tennessee Valley Authority in malaria prevention on impounded waters (USPHS and TVA, 1947). The water level in medium-scale reservoirs can be rapidly lowered either by manual control of the sluice gates or by an automatic siphon device. By careful manipulation of a series of dams on the Tennessee River it was possible to raise the water level transiently to flood height, so stranding flotsam and floating vegetation that tended to harbor vector mosquito larvae. Subsequently, rapid dropping of the water level was able to strand the larvae of *Anopheles quadrimaculatus*, the local malaria

Health Aspects of Lakes and Reservoirs, Table 1 Schistosomiasis and malaria risk from water storage in large dam reservoirs

WHO Region	Schistosomiasis			Malaria	
	At risk from big dams Millions	% of total risk from big dams %	Estimated infected from big dams Millions	Number of big dams Number	People at risk from big dams Millions
<i>Africa S of Sahara</i>	28.71	5.1	9.62	525	3.07
<i>Latin America</i>	1.22	3.4	0.06	1,449	0.48
<i>Middle E and N Africa</i>	2.35	1.7	0.29	812	2.46
<i>SE Asia and W Pacific</i>	10.09	21.7	0.23	6,405	12.33
World	42.36	5.4	10.20	9,191	18.34

The data are derived from Keiser et al. (2005) and Steinmann et al. (2006)

vector, and marshy areas dried out. The malaria vector bred close to the shoreline during May to September. From July, the level gradually recedes some 3 cm per week, but superimposed on this are forced fluctuations of 30 cm approximately weekly which repeatedly strand each generation of the mosquito eggs and larvae. The water regime also kept the larvae clear of emerging vegetation which provides cover for them, and helped the breeding of larvivorous fish. This highly successful approach to malaria control depended upon joint planning by engineers and vector biologists, the particular ecological characteristics of the North American malaria vectors, and the availability of water in the river to allow fluctuation of the water level. The approach has also been used against *Anopheles culicifacies* in South Asia. However, as with most environmental control methods, this is species-specific. Any attempt to use it against puddle-breeding mosquitoes in the African tropics, around reservoirs too large for rapid oscillations of level and with very shallow sloping edges, would be worse than useless: the rate of water level fall would be slow and generate extensive breeding sites for *Anopheles gambiae*, the world's most effective malaria vector, and do more harm than good.

Water level fluctuations have also been considered as a way to strand aquatic snails in Africa, but the estimated drawdown rate required, around a meter per day, is greatly in excess of what seems feasible operationally. Changes in discharge flow rates have also been recommended for *Simulium* control, but this appears speculative, unless the spillway can be dried out. More successful in one site, the origin of the White Nile from Lake Victoria, was positioning of a narrow pipe down through the dam wall so that liquids could be added to the outflow from the sluices. Insecticides were poured down at regular intervals; the turbulence reduced the insecticide particle size down to 1 μ diameter. This size of particle was raked out of the water by the feeding habits of the *Simulium* larvae which were thereby poisoned selectively. Moreover, when this came to an end after some years, it appears that the *Simulium* species that re-invaded the empty ecological niche was of a type that did not bite humans.

Where malaria vectors and other vector mosquitoes are not amenable to environmental control by water level or shoreline manipulation, or where there is residual malaria after they have been applied, other methods need to be used in addition for both prevention and prompt treatment. These include use of insecticide-treated mosquito nets if the vectors are nocturnal and rest indoors, house screening, possible residual insecticide spraying, and use of repellents, as well as sufficiently accessible dispensaries or health centers stocked with locally approved antimalarial medicines for treatment, as severe malaria is a medical emergency requiring immediate action.

Reservoir construction and early filling

There is now much published work on the health hazards of major water storage reservoirs (Stanley and Alpers,

1975; Jobin, 1999). Planning (stage 1) to construct a dam, and even the rumor that this might happen, will lead to a set of social and environmental changes with health consequences of an unplanned as well as an intended nature. The construction phase (stage 2) will greatly intensify these, as there will be immigration of workers, of those hoping to provide services for the workers, and often the beginnings of a health infrastructure. The health problems of transient labor predominate: trauma, sexually transmitted and respiratory infections, and outbreaks of locally endemic diseases if the workers are from a non-endemic area. Funds for infrastructure may enable good facilities for the longer term. The local people displaced from the inundated area almost invariably suffer from inadequate support and lack of planned movement to a suitable site. These indirect health consequences of creating water storage matter, and also provide health opportunities.

The early period after filling the reservoir (stage 3) may see complex biological changes such as rotting forests, explosions of insects, fish, fishermen, and shoreline vegetation with vector habitats being created, leading to outbreaks of schistosomiasis and malaria (in areas of previously low transmission), with gradual progression to a steady state (stage 4) which may or may not include a higher level of health hazards than before. Stages 1–3 comprise a key period or “Chronotone” lying between the original state of the landscape and the final relatively steady state of the mature dam and reservoir (Bradley, 2004). The terminology is by analogy with the term ecotone, which is the area in space that lies between two types of ecosystem whereas the chronotone is an equivalent interval in time rather than space. It includes the structures, water and adjacent land, the ecology, settlement, use and social conditions. Many of the changes that occur during the chronotone are predictable, and others not, so there is a need both to plan the management of expected health hazards and to monitor the situation. It is a key time to invest effort in order to reap long-term reductions in health hazards. While this is also true of small impoundments, the strategy needed is different from that appropriate for large reservoirs. For a big dam, such as that for the Volta Lake, Ghana, the chronotone may last for around two decades.

Small reservoirs

Methods to reduce the health hazards of large reservoirs are well studied, even if often ignored, but those for small dams are less clear, requiring choice appropriate to the locally relevant pathogens and further research attention.

Small multipurpose reservoirs, “tanks” and “dams” are probably collectively more important for health than are large dams, making up in numbers what they lose in capacity. In part of Northern Nigeria there were over 700 in a limited area. Worldwide, in 2001 it was estimated that there were 40,000 large dams and over 800,000 small reservoirs (Keiser et al., 2005), although the last figure is

probably a substantial underestimate. Multiple small reservoirs pose different problems from big dams. Formal control over them is weak, and is exerted at local level by local government and community pressure. The users need to be convinced if health measures are to be implemented and maintained. The various health risk issues have to be balanced against the different uses to which the water will be put. General rules are less applicable and flexible local inputs are needed. Resources are, however, much more limited and many small dams pose major health hazards.

Measures to control the health hazards of small dams are site-specific, but may include avoiding the need to enter the water, by provision of pumps, cattle troughs (but with adequately drained surrounds), sites for laundry and canoe landing stages. These will reduce schistosomiasis risk. Fencing may be used to prevent access of livestock and consequent pollution, and steep edges to the pool deter emergent vegetation and reduce mosquito breeding (although they may create a drowning risk to children unless fenced), while stocking with appropriate small fish may reduce mosquitoes further. The floating fern *Azolla* will also deter mosquito breeding (especially of anophelines) once surface coverage exceeds 90%, which may or may not be acceptable to users. It is difficult to prevent all pollution of surface waters and some form of post-storage treatment is, if possible, needed for drinking water. In the tropics, sanitation is best directed toward pathogen reduction, rather than relying on water treatment to achieve this.

Conclusion

Several broad principles should govern the approach to health issues in developing impoundments of water, whether small or large. These include considering health issues at all stages of the project, from initial plans and design right through to operation and management.

Early advice should be sought from public health experts, particularly those who have worked in the area of the proposed reservoir for many years, both medical biologists and communicable disease epidemiologists. In the case of a large development, an expert epidemiological team will need to make a health opportunity assessment. The issues should be addressed from a co-ordinated but interdisciplinary viewpoint, at all stages.

Research has been concentrated on health hazards of large dams, but in spite of some excellent local studies, work on smaller water storage reservoirs is relatively neglected. More work is needed on these problems, not only in relation to health but also into linked aspects of agriculture, livestock watering, and conservation.

Whatever the scale of water storage, planning for health hazard reduction needs to be undertaken well before the development and construction of new storage. The chronotone, or period of rapid change around the development that is crucial for effective long-term action, is a period of great opportunity to improve health.

The literature on reservoirs and disease transmission is chiefly from the last three decades of the twentieth century when many large dams were built, especially in the tropics, and the two best books are Stanley and Alpers (1975) and Jobin (1999), the former for its broad scope and Jobin for detail on selected areas from a control viewpoint. The water-related disease classification is to be found in White et al. (1972). Keiser and Utzinger's papers have the best estimates of the effects of water development on malaria and schistosomiasis. Birley's (1991) guidelines can be downloaded from the WHO website, as can Bradley and Bos (2010) from the SIWI website.

HYDRODYNAMICS AND CIRCULATION OF FJORDS

Anders Stigebrandt
 Department of Earth Sciences, University of Gothenburg,
 Gothenburg, Sweden

Introduction

Fjords are narrow and deep inlets, carved by glacial processes, with a sill in the mouth. They are typically strongly stratified, often with three clearly distinguishable water masses. The surface water has often reduced salinity due to local freshwater supply. The stratification of the intermediary water, between the surface water and the basin water, continuously mirrors the ever-changing stratification of the coastal water outside the mouth but with some phase delay. The basin, below the sill level, contains the basin water which is the densest water that occurs above sill level in the coastal area, i.e., outside the fjord. Water masses and some physical processes and modes of circulation in fjords are indicated in [Figure 1](#).

Currents in a fjord are generally forced both inside and outside the fjord. The local wind in the fjord forces surface currents that are approximately in the wind direction and with a speed that is a few percent of the wind speed. The wind drift converges toward the shores whereby baroclinic horizontal circulation, often encompassing the upper layers of the whole fjord, is generated. The wind also drives vertical mixing of the surface layer and if there is local freshwater supply to the fjord, wind mixing will sustain so-called estuarine circulation leading to outflow of brackish surface water and inflow of seawater. Remotely forced circulation will proceed in a fjord even under calm conditions. One differentiates between baroclinic circulation that varies vertically and barotropic circulation with uniform velocity in the whole water column. Remotely forced circulations are driven by horizontal pressure gradients, due to differences in vertical

stratification and sea level, respectively, between the fjord and the area outside the fjord.

In this entry, currents due to various modes of circulation are discussed with focus on fundamental dynamic balances and simple formulas that can be used to make first-order estimates of the flow through the mouth and also within fjords. The water exchange with the coastal water is coupled to various modes of forcing and the following externally forced processes and circulation modes are discussed here.

- Intermediary circulation forced by density variations outside the fjord (Section [Intermediary Circulation Forced by Density Variations in the Coastal Water](#))
- Barotropic tidal circulation forced by sea level variations outside the fjord (Section [Barotropic Tidally Driven Circulation](#))
- Estuarine circulation forced by local wind mixing and freshwater supply (Section [Estuarine Circulation](#))
- [Generation of internal tides and jets at sills](#)
- Vertical mixing in fjord basins, ultimately powered by tides and the local wind (Section [Vertical Mixing in Fjord Basins](#))
- Exchange of basin water (below sill level) forced by turbulent mixing (Section [Exchange of Basin Water](#)).
- In addition there is also internally forced wind drift and wind-driven fjord-scale circulation and surface and internal seiches (Section [Wind Drift and Related Phenomena](#)).
- Application of hydrodynamics to fish farming (Section [Hydrodynamics of Fjords Applied to Fish Farming](#)).
- A short summary concludes the entry (Section [Summary](#)).

The aim of this entry is to give an overview of the hydrodynamics of fjords including general modes of circulation with emphasis on basic dynamics. Excellent reviews of the physics of fjords have been written by Gade and Edwards (1979) who concentrated on deepwater renewal, by Farmer and Freeland (1983) who covered several aspects and recently by Inall and Gillibrand (2010) who covered recent contributions to the physics of fjords, and Cottier et al. (2010) who reviewed the physical oceanography of Arctic fjords.

Stratification changes in small fjords due to water exchange and mixing

The waters of many fjords may be treated as 1D because horizontal gradients are much smaller than vertical. The 1D vertical advection–diffusion equation for salinity (temperature, etc.) is then an appropriate starting point for descriptions of large-scale circulation. Consider a horizontal slice (slab) of a fjord centered at the depth z - ([Figure 2](#)). The slice has thickness dz , horizontal surface area $A(z)$, volume $V(z) = A(z)dz$, and salinity $S = S(z)$. Inflow/outflow through the fjord mouth introduces a flow $q = q(z)$ into and out of the fjord which in turn introduces vertical advection of velocity $w(z)$ through the

Hydrodynamics and Circulation of Fjords, Figure 1 Water masses, physical processes, and circulation modes in fjords. The vertical density distribution is shown by $\rho(z)$. Mixing in the basin water occurs essentially at the bottom boundaries.

Hydrodynamics and Circulation of Fjords, Figure 2 Definition sketch for the vertical 1D-model of a fjord basin. The vertical z -axis is directed upward.

horizontal boundaries of the slab. The salinity of water flowing into the slab by the flow $q(z)$ is $S_{in}(z)$. For horizontal flow out of the slab (q is negative) S_{in} equals $S(z)$. Salt is also transported through the horizontal boundaries of a slab due to vertical turbulent diffusion.

Conservation of salt in the slab is described by

$$\frac{\partial S}{\partial t} = \frac{1}{A} \left(\frac{\partial}{\partial z} \left(A \kappa \frac{\partial S}{\partial z} \right) - \frac{\partial}{\partial z} (wAS) + qS_{in} \right) \quad (1)$$

Conservation of volume requires

$$q - \frac{\partial}{\partial z} (wA) = 0 \quad (2)$$

Combination of [Equations 1](#) and [Equations 2](#) gives the following equation for the rate of change of salinity of a slab:

$$\frac{\partial S}{\partial t} = \frac{1}{A} \left[\frac{\partial}{\partial z} \left(A \kappa \frac{\partial S}{\partial z} \right) - wA \frac{\partial S}{\partial z} + q(S_{in} - S) \right] \quad (3)$$

Similar equations may be derived for temperature T and other conservative scalars. If nonconservative substances are considered, e.g., dissolved oxygen, plant nutrients, and various tracers, there should also be sink/source terms in the equations corresponding to [Equations 1](#) and [Equations 3](#). The vertical advection–diffusion model above is discussed in more detail in Stigebrandt (1987, 1990).

If the diffusive term may be neglected compared to the advective terms, [Equation 3](#) simplifies to

$$\frac{\partial S}{\partial t} = \frac{1}{A} \left[-wA \frac{\partial S}{\partial z} + q(S_{in} - S) \right] \quad (4)$$

For depths where there is outflow, $S_{in} = S$ and salinity changes only due to vertical advection. The vertical speed can then be written as

$$w = -\frac{\partial S}{\partial t} / \frac{\partial S}{\partial z} = -\Delta z / \Delta t. \quad (5)$$

The vertical speed w can thus be estimated by the vertical distance Δz that an isohaline (or isothermal) surface moves during the time Δt . For the following example, it is assumed that $\partial S / \partial z$ is negative. With outflow from the upper layers (and inflow to lower layers) w is positive (upward motion) and $\partial S / \partial t$ is positive. With outflow from lower layers, w is negative and $\partial S / \partial t$ is negative. The expression for w becomes more complicated for depths where there is inflow, cf. [Equation 4](#). The total outflow Q_{Out} can easily be estimated from vertical integration of [Equation 2](#):

$$Q_{Out} = \max |Aw| \quad (6)$$

Equations 4, Equations 5, and Equations 6 are typically applicable to the intermediary layer where vertical diffusion usually contributes much less to temporal changes than vertical advection due to intermediary circulation, described in Section “Intermediary Circulation Forced by Density Variations in the Coastal Water” below. They can also be applied to study exchange of basin water by a dense bottom current using continuous observations of the vertical stratification in the basin.

In periods lacking inflow of new basin water, salinity in the basin water changes only due to vertical mixing and Equation 1 may be simplified as follows:

$$\frac{\partial S}{\partial t} = \frac{1}{A} \left[\frac{\partial}{\partial z} \left(A \kappa \frac{\partial S}{\partial z} \right) \right] \quad (7)$$

In this case, horizontally averaged values of κ may be estimated from horizontally averaged vertical profiles observed at two different occasions. Vertical integration of Equation 7 from the greatest depth $z = d$, where there is no diffusive flux of mass (through the sea bottom), to some level $z = u$, gives the following expression for the vertical diffusivity at the level $z = u$:

$$\kappa_{z=u} = \frac{1}{\left(A \frac{\partial S}{\partial z} \right)_{z=u}} \int_b^u \frac{\partial S}{\partial t} A dz \quad (8)$$

This equation may be used to compute κ at $n-1$ levels if there are n levels of observations of $S = S(z, t)$. This method, the so-called budget method, to estimate horizontally averaged values of κ is described at length by Gade (1970) and Gargett (1984). The latter author examined in detail various observational methods of obtaining the vertical diffusivity. She concluded that careful use of budgets of conservative scalars is the only unequivocal method to determine vertical diffusivity. Application of the budget method to cases where the small-scale turbulence is confined to a thin layer near the bottom (boundary mixing) is discussed in Stigebrandt (1976). The budget method to estimate the vertical diffusivity has been applied to numerous fjord basins (see Section Vertical Mixing in Fjord Basins).

Intermediary circulation forced by density variations in the coastal water

Density variations outside a fjord cause horizontal pressure gradients between the fjord and the area outside the fjord. These drive currents through the mouth that tend to adjust the stratification in the fjord to the stratification outside the fjord (Pettersson, 1920). The circulation driven by this mechanism (baroclinic pumping) is called intermediary circulation because it is most apparent in the intermediary layer. It is well known that intermediary circulation may exchange the water above the sill in fjords which explains rapid shifts in pelagic ecology, e.g., Lindahl and Hernroth (1988) and Matthews and Heimdal (1980). It is suspected that intermediary circulation

strongly contributes to rapid circulation of warm subtropical waters in a glacial fjord in Greenland (Straneo et al., 2010). Intermediary circulation is described in Svendsen (1980), Holbrook et al. (1983), and Aure et al. (1996). Arneborg (2004) demonstrated that the amplitude of the annual temperature cycle beneath the surface layer is smaller in the Gullmar Fjord than outside, showing that intermediary circulation is damped as it proceeds into the fjord.

Time-dependent intermediary water exchange through a fjord mouth was computed in Stigebrandt (1990) using a numerical fjord model. The flow was forced by the synoptic horizontal baroclinic pressure gradient in the mouth as determined from the vertical density profiles on both sides of the mouth. Engqvist and Omstedt (1992) made similar computations of intermediary water exchange of a fjord in the Baltic proper. Coupled fjord-ocean numerical models have been used to simulate coast-fjord water exchange driven by density variations in the coastal water, e.g., Klinck et al. (1981), Asplin et al. (1999).

Estimates of the water exchange of many Scandinavian fjords by the box model “Fjordenv,” described in Stigebrandt (2001), show that intermediary water exchange often is larger than the sum of tidal and estuarine water exchange. This is in particular true in fjords with deep mouths.

Density variations in the coastal water

Variations of the vertical density distribution at a coastal site may be caused by variations of the regional wind causing convergence and divergence at the coast and thereby upwelling and down-welling. However, variability of the vertical density distribution at a coastal site may also be caused by advection of horizontal density gradients along the coast.

In many coastal areas, there are observational series that may be used to compute the variability of the density field in coastal water. However, observations are often made with rather low frequency. This means that it is not possible to estimate the correct spectral distribution of the variability because variability at frequencies higher than the Nyquist frequency (i.e., half the observational frequency) will falsely be attributed to lower frequencies. This well-known effect is called aliasing. Here we present the variability at the hydrographical station Lista localized just outside the southwestern tip of Norway (N 58°05'; E 6°32'). Observations started in 1942 and are typically carried out twice a month. About 1,750 vertical profiles have been taken since the start. Lista is one of eight coastal stations regularly monitored by Institute of Marine Research in Bergen. The isopleth diagram in Figure 3 shows the density field observed at Lista in the years 1980 and 1981 when the observational frequency was maximum due to a research program. This plot is based on 98 profiles.

The variance at each observational depth of a hydrographical time series with low temporal resolution, $\text{Var}(\text{tot})$, is here formally partitioned into three parts,

Hydrodynamics and Circulation of Fjords, Figure 3 Observed density field during 1980 and 1981 at Lista. It is readily seen that the variability of the density field cannot be described as only due to vertical advection (by upwelling and downwelling). The contribution by horizontal advection of horizontal gradients is obviously large.

namely, the variance for periods less than 1 year, $\text{Var}(<1)$, the variance for the period exactly 1 year $\text{Var}(=1)$, and the variance for periods longer than 1 year $\text{Var}(>1)$, thus

$$\text{Var}(\text{tot}) = \text{Var}(<1) + \text{Var}(=1) + \text{Var}(>1) \quad (9)$$

The partition is done as follows. One first computes the total variance, $\text{Var}(\text{tot})$, using all data. Thereafter one computes the mean annual cycle described by monthly means and computes the variance of this cycle, $\text{Var}(=1)$. The monthly means are then subtracted from the original data series. The resulting series does not contain the mean annual cycle. Then one computes annual averages. The resulting series only contains long-term, sub-annual variability and the variance of this, i.e., $\text{Var}(>1)$ is computed. Using Equation 9, the variability of short-term fluctuations is then given by $\text{Var}(<1) = \text{Var}(\text{tot}) - \text{Var}(=1) - \text{Var}(>1)$. Of course, this is only approximately correct due to aliasing as discussed above.

The results of an analysis applied to the time series from Lista are shown as the standard deviation σ_p which is the square root of the variance (Figure 4). It can be seen that the variability decreases with depth. Short-term variability is greater than the variability of the annual density cycle but the difference decreases with depth. Sub-annual variability is substantially smaller than the other two components. However, as will be discussed in Section “Exchange of Basin Water” below, the variability at lower frequencies may be important since it may determine the

Hydrodynamics and Circulation of Fjords, Figure 4 Standard deviation of the density field at Lista has been partitioned into three period bands, see legend.

residence time of basin water in fjords where the rate of vertical mixing in the basin water is relatively weak.

By studying the variance around the monthly means at Lista, it is found that the largest variability in the upper

layers, from sea surface and down to about 25 m depth, occurs in summer and autumn. From 50 m depth and deeper, the largest variability occurs in autumn.

The variability of the density field at Torungen and Jomfruland outside the Norwegian Skagerrak Coast was observed during 1 year by Aure et al. (1996) using moored instruments. Observations were recorded every tenth minute to avoid aliasing. They found that about half of the variability occurs for periods of 1 month and longer. Periods of 1 week and shorter contribute about 25% of the total variance in the upper 20 m but the contribution decreases to about 10% at 70 m depth. Gustafsson and Stigebrandt (1996) described the horizontal distribution of the variability of the density field in Skagerrak using the ICES database.

A simple empirical model of intermediary circulation

The intermediary circulation was for a long time quite anonymous. A probable reason for this is that there was no simple model or formula to estimate it. Stigebrandt and Aure (1990) used the numerical model in Stigebrandt (1990) to compute the intermediary circulation Q_i in a spectrum of fjords driven by a 1-year-long series of weekly observed vertical density profiles obtained in the coastal water in Møre and Romsdal, Norway. From the model results, they derived the following empirical formula:

$$Q_i = \gamma \left(g B_m H_t A_f \frac{\Delta M}{\rho_0} \right)^{1/2} \quad (10)$$

Here γ is a nondimensional empiric coefficient that equals $17 \cdot 10^{-4}$. B_m is the width of the mouth, H_t the sill depth, A_f the horizontal area of the fjord at sea surface, g the constant of gravity, and ρ_0 a reference density.

As a measure of the forcing of the flow, they used ΔM , which is the standard deviation of the weight M of the water column from mean sea level down to sill level (kg m^{-2}). ΔM is estimated by vertical integration of the standard deviation of coastal water density $\sigma_\rho(z)$ from the sea surface down to sill level, thus

$$\Delta M = \int_0^{H_t} \sigma_\rho(z) dz \quad (11)$$

According to Equation 10 the forcing of the intermediary circulation is proportional to $\Delta M^{1/2}$. Note that Equation 10 should give the long-term mean of the intermediary circulation in a fjord. Inflow and outflow are equally large ($=Q_i$) since the circulation is baroclinic. For fjords with relatively narrow mouths, the current speeds may be quite large and in this case the flow may be hydraulically controlled and another formula should be used to estimate the intermediary exchange, see Stigebrandt (1990).

Aure et al. (1996) discussed the contribution from different periods to the forcing of the intermediary circulation

arguing that higher frequencies should be more efficient than lower frequencies. They suggested that ΔM should be modified to accommodate for the frequency dependence. It would probably be more relevant to use only the high-frequency part of the variance, at least for smaller fjords. Arneborg (2004) found that higher frequencies are most important for intermediary water exchange in the Gullmar Fjord.

Longitudinal variations of intermediary currents in the fjord

The current direction changes over time between ingoing and outgoing. It also changes vertically and most of the time the current probably has a two-layer structure as can be seen in the simulations by Stigebrandt (1990). Multilayer structure appears to evolve when the forcing is weak. The transport into the fjord is always equal to the transport out of the fjord. Due to vertical stratification, intermediary circulation is usually restricted to levels above sill level. It is only when the inflowing water is so dense that it can replace the basin water that intermediary circulation contributes to currents below sill depth.

The mean speed in the mouth U_i due to intermediary circulation equals

$$U_i = 2Q_i/A_m \quad (12)$$

Here $A_m = B_m H_t$ is the vertical cross-sectional area of the mouth and mean intermediary transport Q_i is given by Equation 10. Maximum currents should be a factor 2–4 greater than U_i , an analysis of the density field outside the fjord may be necessary to estimate this factor that may be different for different coastal stretches.

Assuming that the period of vertical motions induced by the coastal density field is long compared to the travel time of internal waves from the mouth to the head of the fjord, it may be assumed that the amplitude of vertical motion is similar in the whole fjord. The transport at a certain distance from the mouth should then be proportional to the area of the fjord inside the location. Introduce a longitudinal coordinate in the fjord such that the head of the fjord is at $x = 0$ and the mouth of the fjord at $x = L$. At the distance x from the head of the fjord (along the major fjord axis) the transport should be given by the following equation

$$Q_i(x) = Q_i \cdot \frac{A(x)}{A_f} \quad (13)$$

Here $A(x)$ is the horizontal surface area of the fjord inside the horizontal coordinate x and $A_f = A(L)$.

Mean speed forced by intermediary circulation at the distance x from the head of the fjord then equals

$$U_i(x) = U_i \frac{A_m}{B(x)H_t} \cdot \frac{A(x)}{A_f} \quad (14)$$

Here $B(x) \cdot H_t$ is the vertical cross-sectional area of the fjord above sill depth at distance x from the head. This

formula does not accommodate for damping of intermediary circulation with increasing distance from the mouth as found by Arneborg (2004) for the Gullmar Fjord.

Barotropic tidally driven circulation

Mean speed U_t through the mouth caused by a surface tide equals

$$U_t = \frac{dh}{dt} \cdot \frac{A_f}{A_m} - \frac{Q_f}{A_m} \quad (15)$$

Here A_f is the horizontal surface area of the fjord, A_m the vertical cross-sectional area of the mouth, dh/dt the rate of mean sea level change in the fjord, and Q_f the rate of freshwater supply to the fjord.

Together with a simple model of barotropic flow through straits giving the speed as a function of the sea level difference between the basins on the two sides of the strait, Equation 15 can be used to study tidal choking, see Stigebrandt (1980a, 1980b) and Wickbom and Rydberg (1996). If the speed is greater than the speed of internal waves in the neighboring basins, tidal flow through the strait will generate tidal jets close to the strait and not internal tides in the neighboring basins, see Section “Generation of Internal Tides and Tidal Jets at Sills”. A thorough analysis of observations from Loch Etive by Inall et al. (2004) shows a more complex picture.

Longitudinal variations of barotropic currents in the fjord

The first mode tidal response is a standing wave with a wavelength four times the length of the fjord and with a node in the mouth.

If one starts from the momentary transport Q_t , it is relatively simple to describe how the barotropic current amplitude changes from the mouth to the head of the fjord, thus

$$U_t(x) = U_t \frac{A(x)}{A_f} \frac{A_m}{A_{\text{vert}}(x)} \quad (16)$$

Here again $A(x)$ is the horizontal surface area of the fjord between the head and the distance x from the head and $A_{\text{vert}}(x)$ is the vertical cross-sectional area of the fjord at the distance x from the head (the vertical cross-sectional area at the mouth equals $A_m = A_{\text{vert}}(L)$). The speed will have local maxima where the vertical cross-sectional area has local minima. The barotropic response to tidal forcing of fjords was reviewed in Stigebrandt (1980a).

Present-day numerical tidal models are capable of computing very realistic barotropic tides and tidal currents, e.g., Davies et al. (2011) who compare different types of models.

Estuarine circulation

Freshwater that is supplied to a fjord by runoff and precipitation accumulates at the sea surface. Wind mixing may entrain underlying seawater into the surface layer which then becomes brackish. The outflow of brackish surface water is forced by the higher pressure of the surface layer

in the fjord than outside the fjord. It was shown by Stommel and Farmer (1953) that the surface water will attain the speed of a stationary internal wave when flowing through a topographic constriction in the mouth. Assuming that the stratification can be described by two superposed layers, the speed and thickness of the upper layer are U_{1m} and H_{1m} , respectively, and the speed and thickness of the lower layer U_{2m} and H_{2m} , respectively. The flow in a topographically constricted mouth can then be described by the following equation derived by Stommel and Farmer:

$$\frac{U_{1m}^2}{g'H_{1m}} + \frac{U_{2m}^2}{g'H_{2m}} = 1 \quad (17)$$

Here g' is the reduced gravity which equals $g \cdot \Delta\rho/\rho$ where $\Delta\rho$ is the density difference between the layers. This equation gives the relationship between the rate of flow through the mouth and the vertical stratification in the fjord at the mouth.

Under stationary conditions conservation of volume requires

$$Q_1 = Q_f + Q_2 \quad (18)$$

Here $Q_{1(2)}$ is outflow (inflow) through the mouth and Q_f is the supply of freshwater.

Conservation of salt requires

$$Q_1 S_1 = Q_2 S_2 \quad (19)$$

Here $S_{1(2)}$ is the salinity of brackish water (seawater).

If the effect of temperature may be ignored, the density of the brackish water may be written as

$$\rho = \rho_f(1 + \beta S) \quad (20)$$

Here ρ_f is the density of freshwater, β the coefficient of salt contraction ($\approx 0.0008\%^{-1}$), and S salinity (‰).

Due to acceleration toward the mouth, the thickness of the upper layer is greater in the (wider) fjord H_1 than in the (narrower) mouth H_{1m} , thus

$$H_1 = \phi H_{1m} \quad (21)$$

The coefficient ϕ is the ratio between the thicknesses of the surface layer in the fjord and in the mouth. Observations in fjords give ϕ -values in the range 1.5–2.7, see Green et al. (2004).

The flow of seawater into the surface layer is due to entrainment w_e performed by the wind-driven turbulence in the surface layer. The total flow by entrainment equals the horizontal surface area of the fjord A_f times w_e , thus

$$Q_2 = w_e A_f \quad (22)$$

The rate of entrainment can be computed from the following equation:

$$w_e = \frac{m_0 u_*^3}{g'H_1} \quad (23)$$

Here the empirical constant $m_0 = 0.6$ (Stigebrandt, 1985) and H_1 is the thickness of the upper layer in the fjord and u_* the friction velocity that equals the square root of the kinematic wind stress. If one assumes that the lower layer is thick and moves with low velocity Equation 17 degenerates to $U_{1m}^2 = g'H_{1m}$. For this case the following analytical solution for the thickness H_1 and the salinity S_1 of the surface layer may be obtained (Stigebrandt, 1981a):

$$H_1 = \frac{N}{2Q_f M} + \varphi \left(\frac{Q_f^2}{MB_m^2} \right)^{\frac{1}{3}} \quad (24)$$

$$S_1 = \frac{S_2 N}{N + 2\varphi \left[Q_f^5 \left(\frac{M}{B_m} \right)^2 \right]^{\frac{1}{3}}} \quad (25)$$

Here A_f is the area of the fjord, B_m the width of the mouth, W mean wind speed, $M = g\beta S_2$ and $N = C_e W^3 A_f$ where $C_e = 2.5 \cdot 10^{-9}$ is an empirical constant that contains among others the drag coefficient for air flow above the sea surface.

The first term on the right-hand side of Equation 24 is the Monin-Obukhov length determined by the buoyancy flux ($=g\beta S_2 Q_f / A_f$) and wind mixing ($\sim W^3$). The second term is the freshwater thickness, H_{1f} , determined by the hydraulic control. Using long series of observations of hydrographical profiles and freshwater supply, Green et al. (2004) showed that $H_{1f} \sim Q_f^{2/3}$ in Holandsfjord, Norway as predicted by the theory above. They also showed the power P spent on mixing (diapycnal buoyancy fluxes) is about 0.5 mW m^{-2} . If the efficiency of turbulence with respect to buoyancy fluxes R_f equals 0.06 (see Section Vertical Mixing in Fjord Basins below), the mean supply of power P/R_f is about $6\text{--}7 \text{ mW m}^{-2}$ from the wind to the surface layer. For comparison, Gustafsson and Stigebrandt (1996) estimated the mean wind power supply to Skagerrak to be about 36 mW m^{-2} . This difference might be reasonable because Holandsfjord is sheltered by very high mountains surrounding the fjord.

The model presented here should be valid for fjords with mouths narrower than the internal or baroclinic Rossby radius, i.e., $B_m < R_{oi}$ where $R_{oi} = c_i/f$. Here c_i is the speed of the internal wave in the stratification under consideration and f is the Coriolis parameter. The present author applied the fjord model to the Arctic Ocean that has mouths wider than R_{oi} (Stigebrandt, 1981b). The flow control equation, Equation 17 was replaced by the following equation relating geostrophic baroclinic transport to upstream stratification in a system with a deep lower layer, thus

$$Q_1 = \frac{g'H_1^2}{2f} \quad (26)$$

The freshwater content of the surface layer in Kattegat has been shown to be governed by a rotating hydraulic

control as expressed by Equation 26, see Stigebrandt and Gustafsson (2003).

Velocities caused by estuarine circulation

When the freshwater supply and the salinity of the brackish surface layer is known, one may compute the transport in the two layers

$$Q_1 = \frac{Q_f S_2}{S_2 - S_1} \quad (27)$$

$$Q_2 = \frac{Q_f S_1}{S_2 - S_1} \quad (28)$$

The speed U_e of the estuarine circulation inside the mouth can be estimated from the following expression:

$$U_e(x) = \frac{Q_1(x)}{B(x)H_1} \quad (29)$$

The transport $Q_1(x)$ varies with the distance from the source. There may be several sources at different longitudinal coordinates x and there may be different rates of initial mixing between freshwater and seawater in the mouths of the sources. The speed of the so-called compensation current in the lower layer is usually assumed to be weaker because it is assumed to be thicker. This is discussed by Stigebrandt and Molvaer (1996) who question if this is true for fjords with strong stratification beneath the surface layer.

Generation of internal tides and tidal jets at sills

Tides may supply huge amounts of energy to internal waves and jets that may feed turbulence and diapycnal mixing processes in fjords and, in particular, in the basin water where both wind-driven and intermediary circulation normally have small amplitudes. Internal tides and jets are also important in fjords because they may give strong contributions to the current field close to sills.

In stratified systems, harmonic currents driven by astromonic tides may generate internal waves at sloping bottoms. Stigebrandt and Aure (1989) differentiated between wave basins and jet basins. Basins in which internal tides are generated at sills are called wave basins. In jet basins, the tidal speed at the sill is greater than the speed of internal waves in the neighboring basin and tidal jets are generated.

To compute the generation of internal tides at fjord sills, it is assumed that surface and internal tides together fulfill the condition of vanishing flow normal to the bottom, e.g., Stigebrandt (1976, 1980b); Stacey (1984). This gives the amplitude of the internal tide for specified sill geometry and barotropic tidal flow.

Fjords often have a pycnocline at sill depth because the densest water appearing outside and above the fjord sill will fill the basin below the sill level, cf. Section "Exchange of Basin Water" below. The vertical stratification is then well approximated by two

homogeneous layers with the interface at about the sill depth, see Figure 5 for definitions.

If there were no sill at $x = 0$, the barotropic tidal speed would be

$$u_b = \alpha \cos(\omega t) \quad (30)$$

The amplitude α of the speed is given by topographical factors of the fjord and mouth, the frequency ω , and the sea level amplitude a_f of the tide in the fjord, which for simplicity is assumed to be the same in all parts of the fjord, thus

$$\alpha = \omega a_f \frac{A_f}{B_m(H_t + H_b)} \quad (31)$$

The barotropic and baroclinic tides together satisfy the condition of vanishing horizontal speed at the vertical sill, thus

$$u_b + u_{2i} = 0 \quad (32)$$

This gives the following orbital speeds in the upper and lower layers:

$$u_{1i} = \alpha \frac{H_b}{H_t} \cos(kx \pm \omega t) \quad (33)$$

$$u_{2i} = -\alpha \cos(kx \pm \omega t) \quad (34)$$

The waves are progressive and move away from the sill along the x -axis. The wave number κ is defined by

$$\kappa = \frac{\omega}{c_i} \quad (35)$$

The speed c_i of an internal wave in two-layer stratification equals

$$c_i = \sqrt{g \frac{\Delta \rho}{\rho_0} \frac{H_t H_b}{H_t + H_b}} \quad (36)$$

Hydrodynamics and Circulation of Fjords, Figure 5 Definition of a two-layer system in a fjord with a vertical sill at $x = 0$. The water depth in the fjord is H and the sill depth is H_t and $H_b = H - H_t$. Internal waves are generated at the sill. The density is ρ_1 (ρ_2) and the orbital velocity is u_{1i} (u_{2i}) in the upper (lower) layer.

Here g is the acceleration of gravity and $\Delta \rho = \rho_2 - \rho_1$ and ρ_0 is a reference density. For wave generation it is required that $u_{1i} < c_i$ and $u_{2i} < c_i$. If these conditions are not fulfilled, the fjord should be a jet fjord. However, it seems that internal tides to some extent may be generated even in jet fjords by a decaying jet, see Section “Verification of the Model of Energy Transfer To Internal Tides” below.

Evidence shows that internal tides generated at fjord sills are progressive. The prominent internal tides at Dröbak sill in the Oslo Fjord, see Figure 6, are progressive and radiate away from both sides of the sill as shown using current and density observations from moored instruments (Stigebrandt 1979).

The orbital speeds u_{1i} , u_{2i} will be greatest close to the generating sill and decrease away from the sill because the waves may break and also because the basin usually becomes wider and deeper. One should expect that internal tides are radiating from all sills within fjords that generate internal waves.

Both the surface tide and internal tides may give important contributions to the current field in fjords. This should be particularly true in the basin water, beneath the sill level where the contributions from wind-driven and intermediary currents usually vanish.

The following densimetric Froude Number F_d can be used to theoretically differentiate between wave and jet basins:

$$F_d = \frac{\alpha}{c_i} \frac{H_b}{H_t} \quad (37)$$

In laboratory experiments, it was found that internal waves were generated only if $F_d \leq 1$ (subcritical flow). For supercritical flow a jet or rotor developed at the lee side of the sill (Stigebrandt, 1976). If $H_b/H_t < 1$, i.e., for deep sills, the Froude number should be $F_d = \alpha/c_i$.

The model of generation of internal tides in a two-layer stratification presented above has been generalized to continuous stratification where instead a spectrum of internal waves satisfies the boundary condition together with the barotropic flow, e.g., Stigebrandt (1980b) who presented analytical solutions for the case of constant- N vertical stratification. Stacey (1984) and Sjöberg and Stigebrandt (1992) computed the baroclinic response at topography for arbitrary vertical stratification. Tverberg et al. (1991) used a numerical ocean model to study internal wave generation in fjords. They found strong response for internal waves in form of rays radiating out from sills. Several papers during the last years report studies of internal wave generation at sills using numerical ocean models, e.g., Berntsen et al. (2008).

Energy transfer to internal tides and jets at sills

The time-mean energy radiation from the generating sill by a progressive internal wave mode equals

$$P_T = B \cdot E \cdot c_{ig} \quad (38)$$

Hydrodynamics and Circulation of Fjords, Figure 6 Two days of observations inside the sill at Oscarsborg in the Oslo Fjord (sill depth ~ 18 m). The range of the semidiurnal surface tide is about 0.3 m while the range of the internal tide is about 10 m.

Here B is the width of the sill and c_{ig} the group velocity. The energy density E of a long internal wave of period T can be computed from

$$E = \frac{1}{T} \int_0^T \int_0^H \rho \cdot u_i^2 dz dt \quad (39)$$

Here $u_i(z)$ is the wave orbital speed and H the water depth in the adjacent basin. It has been assumed that the effect of Earth's rotations can be neglected in narrow fjords so that the contributions by potential and kinetic energy are equally large.

The mean energy flux into sill-generated long internal tides for two-layer stratification is (Stigebrandt, 1976)

$$P_T = B\omega^2 a_f^2 \frac{A_f}{2A_m} \frac{H - H_t}{H} c_{ig} \quad (40)$$

Here ω is the tidal frequency, a_f the sea level amplitude of the surface tide in the fjord, A_f (A_m) the horizontal area of the fjord (the vertical cross-sectional area of the sill section), H_t the sill depth, and H the mean depth of the fjord. The group velocity c_{ig} for long internal waves in two-layer stratification equals the phase velocity c_i given by Equation 36.

A jet develops on the lee side if the tidal flow over the sill is supercritical, $F_d > 1$, cf. Equation 37. The mean transfer of tidal power to a tidal jet flowing into the fjord equals (Stigebrandt and Aure, 1989)

$$P_{Tj} = 0.42\rho_0 u_0^3 \frac{A_m}{4} \quad (41)$$

Here u_0 is defined by

$$u_0 = a_f \omega \frac{A_f}{A_m} \quad (42)$$

The mean tidal power transferred to a jet flowing out of the fjord is equally large but it dissipates outside the fjord and cannot contribute to mixing in the fjord. Equation 41 accounts for this.

The tidal jet is primarily a barotropic phenomenon, caused by the large-scale topographic resistance formed by the sill section. However, the jet may induce various baroclinic phenomena like hydraulic jumps and high-frequency internal waves, e.g., Farmer and Freeland (1983). In the specific downstream vertical cross section where the speed of the jet has been reduced to the speed of the fundamental internal wave mode, the jet may excite an internal tide as observed in Sechart Inlet (Tinis, 1995; Tinis and Pond, 2001) and in Loch Etive (Inall et al. 2004). Some of the jet energy may in this way be transmitted to the basin water, see also Section “Vertical Mixing in Fjord Basins.”

Supported by qualitative observations of a laboratory experiment of generation of internal tides in a two-layer stratification, it was suggested that most of the energy in internal tides dissipate in the lower layer (Stigebrandt, 1976). In the following, it is assumed that this is true. Some estimates of normalized tidal energy supply to the basin water of fjords are presented in Table 1. It can be seen that the energy supply varies by three orders of magnitude. Some fjord basins receive more energy per unit horizontal surface area than does the abyssal ocean. Fjords are generally one or two orders of magnitude shallower than the ocean. In the basin water of highly energetic

fjords, the mean intensity of tidally forced turbulence may therefore be several orders of magnitude greater than the mean for the abyssal ocean, see also Section “[Vertical Mixing in Fjord Basins](#).”

For comparison it might be interesting to know the energy supply by winds. In [Table 2](#) it can be seen that the power supply by winds to deeper water layers is generally smaller than the supply by tides. However, the energy supply by wind to the surface layer in Holandsfjord was estimated to 6–7 (mW m^{-2}), see Section “[Estuarine Circulation](#).” A comparison with the supply to deeper layers in [Table 2](#) suggests that most wind energy is dissipated in the surface layers and only a small fraction is transmitted to lower layers.

Verification of the model of energy transfer to internal tides

The model of barotropic to baroclinic energy transfer at sills has been verified using several independent methods, see [Figure 7](#) for an overview of methods. The tidal phase lag ϕ across sills caused by the resistance to barotropic tidal flow induced by baroclinic wave drag can be computed (method 1), and theoretical estimates have been

verified for several fjords, e.g., Stigebrandt (1999). The predicted damping of barotropic seiches due to baroclinic wave drag at sills (method 2) has been verified for the Gullmar Fjord (Parsmar and Stigebrandt, 1997). The predicted rates of buoyancy fluxes due to vertical mixing driven by internal tides (method 3) have been verified for many fjords, see Section “[Vertical Mixing in Fjord Basins](#)” below. The intuitively most obvious method to verify models of baroclinic wave drag is to compare computed and observed internal tide radiation away from a sill (method 4). However, this method is difficult to apply in many fjords because internal tides often lose much of their power already close to the sills where they are generated, cf. deYoung and Pond (1989); Stigebrandt (1999); and Arneborg et al. (2004a).

The process of energy transfer from other motions to baroclinic waves may also give rise to flow resistance or drag and may therefore be denoted baroclinic wave drag, see Stigebrandt (1999) for examples of flow resistance.

Vertical mixing in fjord basins

Observations in fix points show turbulence as high-frequency fluctuations of velocity, salinity, temperature, and other state variables. The vertical flux of, for instance, sea salt may be estimated as the time average of the product of the fluctuating components of the vertical velocity w' and the salinity S' , respectively. It is common to describe the turbulent vertical flux of a scalar as a product of the vertical turbulent or eddy diffusivity κ and the vertical gradient of the scalar. For a given locality, it is reasonable to assume that the same value of κ may be used to compute vertical turbulent transports of different scalars. Thus, for vertical fluxes of salt S and temperature T one obtains

$$\kappa \cdot \frac{\partial S}{\partial z} = \overline{w'S'} \quad (43)$$

$$\kappa \cdot \frac{\partial T}{\partial z} = \overline{w'T'} \quad (44)$$

Here z is the vertical coordinate, increasing upward. Similar expressions can be formulated for vertical fluxes of other scalars.

Hydrodynamics and Circulation of Fjords, Table 1 Some published estimates of the energy transfer from tides to internal tides and tidal jets fjords. The figures are normalized by the horizontal surface area A_t of the fjords at sill depth. For comparison, estimates of the mean energy transfer to internal tides in the deep ocean (below 1,000 m depth) are also shown

Fjord, name	P_T/A_t (mW m^{-2})	Reference
Oslo Fjord (Vest Fjord)	7	Stigebrandt (1976)
20 Norwegian wave fjords	0.8–5	Stigebrandt and Aure (1989)
Gullmar Fjord	0.5	Arneborg and Liljebladh (2001b)
Ringdals Fjord	25	Johnsson et al. (2007)
The Ocean (below 1,000 m)	3 4	Egbert and Ray (2001) Sjöberg and Stigebrandt (1992)
9 Norwegian jet fjords	2–142	Stigebrandt and Aure (1989)

Hydrodynamics and Circulation of Fjords, Table 2 Some published estimates of the energy transfer P_W from winds to the layers beneath the surface layer. The figures are normalized by the horizontal surface area A_t of the fjords at sill depth except for the Baltic where the surface area at the depth of the halocline (70 m) has been chosen

Fjord, name	P_W/A_t (mW m^{-2})	Reference
Gullmar Fjord (surface + internal seiche)	0.5 ($R_f = 0.06$)	Arneborg and Liljebladh (2001b) (see comment at the end of Section “ Wind Drift and Related Phenomena ”)
Norwegian fjords	0.3 ($R_f = 0.06$)	Stigebrandt and Aure (1989)
Lake Alpnach (weak winds, about 3 ms^{-1})	0.12	Wüest et al. (2000)
Baltic proper (required to explain the observed vertical mixing of the deepwater)	1 ($R_f = 0.08$)	Axell (1998)

An equation for the turbulent flux of density $\overline{w'\rho'}$ may be obtained using the equation of state for seawater:

$$\rho = \rho_0(1 - \alpha T + \beta S) \quad (45)$$

where ρ is density, α the coefficient of heat expansion, and β the coefficient of salt contraction. If Equations 43 and Equations 44 are multiplied by $\rho_0\beta$ and $\rho_0\alpha$, respectively, and the latter resulting product is subtracted from the former and using the equation of state, the following equation may be obtained:

$$\kappa \cdot \frac{\partial \rho}{\partial z} = \overline{w'\rho'} \quad (46)$$

Buoyancy is denoted by $g' = g\rho'/\rho_0$, where g is the acceleration of gravity, ρ' the fluctuating part of the density, and ρ_0 a reference density. The buoyancy flux $b = \overline{w'g'}$ is obtained if Equation 46 is multiplied by g/ρ_0 , thus

$$\overline{w'g'} = \kappa \cdot N^2 \quad (47)$$

Here $N^2 = -g/\rho_0(\partial\rho/\partial z)$ is the buoyancy frequency. The buoyancy flux b expresses the rate of work against the buoyancy forces (per unit mass, i.e., Watt kg^{-1}) performed by mixing processes in stratified fluids.

In a closed volume containing stratified fluid, turbulent energy cannot escape, neither by radiation of gravity waves nor by advection and diffusion. Only a fraction of the available turbulent power p is used for work b against the buoyancy forces while the remainder ε dissipates to heat by molecular friction, thus

$$b + \varepsilon = p \quad (48)$$

It is often assumed that b is a fixed fraction R_f of p , thus $b = R_f \cdot p$. The so-called flux Richardson number, R_f , is the efficiency of turbulence with respect to execution of buoyancy fluxes. Using $\varepsilon = (1 - R_f)p$ and Equation 47, the buoyancy flux can be expressed in terms of R_f and ε as

$$\kappa \cdot N^2 = \frac{R_f}{1 - R_f} \cdot \varepsilon \quad (49)$$

Hydrodynamics and Circulation of Fjords, Figure 7 Four different methods to verify the model of energy transfer to internal tides at fjord sills are indicated in the figure.

This equation can be used to estimate κ if the dissipation ε can be estimated from observations of so-called micro-structure and R_f is known. The numerical value of the efficiency factor R_f is discussed below.

Power from tides P_T and winds P_W sustains the turbulence in the basin water of fjords. In analogy with Equation 48, it may be assumed that some of the power is used for buoyancy fluxes P_B while the remainder dissipates to heat P_D , thus $P_B + P_D = P_T + P_W$. The power P_B used for buoyancy fluxes is assumed a fixed fraction R_f of the power supply, thus

$$P_B = R_f(P_T + P_W) \quad (50)$$

This equation may be regarded as a definition of the overall (or system or bulk) flux Richardson number R_f .

The total rate of work against the buoyancy forces, P_B , by mixing processes in the basin water of a fjord is obtained by integration of the buoyancy flux, from greatest depth $z = d$ to the sill level $z = h$, thus

$$P_B = \int_b^h \rho_0 \kappa(z) N(z)^2 A(z) dz \quad (51)$$

Thus, P_B can be computed from Equation 51 if the horizontal mean diffusivity $\kappa(z)$ has been estimated for a fjord basin using the budget method described in Section “Stratification Changes in Small Fjords Due to Water Exchange and Mixing.”

Several authors have published estimates of the rate of work against the buoyancy forces using Equation 51. In Figure 8, the observed work against the buoyancy forces, $W = P_B/A_t$ has been plotted against the energy transfer by internal tides to the basin water $E_2 = P_T/A_t$. Comparing the regression line as written down in Figure 8 with

Hydrodynamics and Circulation of Fjords, Figure 8 Observed buoyancy fluxes versus theoretically estimated energy flux to internal tides in fjord basins in Møre and Romsdal (From Stigebrandt and Aure, 1989).

Equation 50 shows that the slope of the line equals the flux Richardson number, thus $Rf \approx 0.066$, and the interception of the fitted line with the vertical axis is RfP_W . This gives $P_W \approx 0.3 \text{ mWm}^{-2}$, see also Table 2. Figure 8 shows that there is a very good correlation between observed buoyancy fluxes and theoretical power supply to turbulence in the basin water. The flux Richardson number estimated here is the bulk flux Richardson number. Similar values of the bulk flux Richardson number has been estimated for many fjord basins, starting with Stigebrandt (1976) who estimated $Rf = 0.05$ for the Oslo Fjord. The rigorous analysis of the Gullmar Fjord by Arneborg and Liljebladh (2001b) gave $Rf = 0.07$.

For jet fjords, Stigebrandt and Aure (1989) found that $Rf = P_{Tj}/A_t$ is only about 0.01. They suggested that this is because the jets are dissipated essentially above the sill basins and only a smaller fraction of the jet energy P_{Tj} is transmitted to the basin water, cf. Tinis and Pond (2001) and Inall et al. (2004).

The bulk flux Richardson number as determined from observed buoyancy fluxes in fjord basins and estimates of the energy supply from tides are typically in the range 0.06–0.07 for wave basins which is less than half of the value 0.2 often used in oceanography. However, Arneborg (2002) has explained why the patch flux Richardson number is about twice the overall flux Richardson number.

Coupling vertical mixing and energy supply to turbulence

Based on some seasonally averaged diffusivities in lakes and fjords, Gargett (1984) suggested that the diffusivity in the deepwater of the Ocean should be proportional to N^{-1} , thus

$$\kappa = \alpha_0 \cdot N(z)^{-1} \quad (52)$$

Here α_0 is an empirical intensity factor (velocity squared) accounting for the mean mixing activity of turbulence. Using the relationship given in Equation 49 between κ and ε and assuming $Rf = 0.2$, Gargett (1984) estimated $\alpha_0 = 1 \cdot 10^{-7} \text{ m}^2 \text{ s}^{-2}$ from available estimates of dissipation ε from the open ocean.

Starting from the parameterization of κ in Equation 52 and using Equation 51 as an integral condition, one may develop the following parameterization of the horizontal and time mean $\kappa(z)$ as function of forcing $P_T + P_W$ and stratification $N(z)$, thus

$$\kappa = \frac{W}{\rho_0 H_b M} N^{-1} \quad (53)$$

Here $W = P_B/A_t = Rf(P_T + P_W)/A_t$ is the power used for buoyancy fluxes by mixing in a vertical column of a basin with upper horizontal surface area A_t , H_b is the mean thickness of the deepwater layer, and M the area weighted vertical mean of N in the basin water of volume V_b defined by

$$M = \frac{1}{V_b} \int_d^h N(z) A(z) dz \quad (54)$$

A slightly more detailed parameterization was developed by Stigebrandt and Aure (1989). This included a fjord-specific constant depending on both stratification and topography.

The parameterization by Stigebrandt and Aure (1989) is probably the first example in oceanography of a relationship between the vertical diffusivity in a stratified water column and the theoretically estimated external forcing W of the turbulence. This equation implies that the vertical diffusivity can be predicted in fjords as long as the forcing can be estimated from tidal amplitude, stratification, and topography. Simple methods to estimate P_T are described in Section “Generation of Internal Tides and Tidal Jets at Sills.” However, in fjords with weak tides, like the Gullmar Fjord (see Tables 1 and Tables 2), the wind contribution P_W may be important (Arneborg and Liljebladh, 2001b).

Observations of mixing in fjords

The budget method has been applied to numerous fjord basins to estimate the vertical diffusivity. Gade (1970) obtained for the Vestfjord values in the interval $0.07 < \kappa < 20 \text{ (cm}^2 \text{ s}^{-1})$ and for Bunnefjord generally lower values. Svensson (1980) used both sea salt and a basin-wide cloud of Rhodamine B in the Byfjord, Sweden and got values in the interval $0.005 < \kappa < 0.06 \text{ (cm}^2 \text{ s}^{-1})$. Smethie (1980) used salt and radon-222 (forming at the decay of radium-226 stored in the sediment) as tracers in a number of Canadian fjords and got values in the interval $0.08 < \kappa < 9 \text{ (cm}^2 \text{ s}^{-1})$. Stigebrandt and Aure (1989) estimated the vertical diffusivity in about 30 Norwegian fjord basins. Values as low as about twice the molecular diffusivity of salt were obtained in Framvaren, a deep and almost tied off and tide-less fjord near the southwestern tip of Norway (Frøyland, 1966).

A cloud of Rhodamin B was released in the basin water of inner Oslo Fjord (Bjerkeng et al., 1978). In the initial phase, the horizontal area of the tracer cloud was small compared to the area of the fjord and the cloud had no contact with the bottom boundary. During this phase, the vertical diffusivity, as computed from the evolution of the tracer cloud, was an order of magnitude less than the vertical diffusivity as estimated from the budget method applied to salt. In Stigebrandt (1979), this observation was taken as evidence for dominance of boundary mixing as anticipated already in Stigebrandt (1976). Similar results were obtained in an Arctic fjord where short-term measurements of vertical diffusion of a radioactive tracer injected at different depths gave about ten times smaller diffusivity than salt-derived values (Lewis and Perkin, 1982). A tracer experiment in Loch Etive showed the dispersion structure of boundary mixing driven by breaking internal waves (Inall, 2009). From observations of

microstructure profiles, Inall and Rippeth (2002) found that the vertical eddy diffusivity is about $0.5 \text{ (cm}^2\text{s}^{-1}\text{)}$ in the deepwater of the Clyde Sea. This is about half of the horizontal and time mean value expected from the budget method. The authors concluded that the mixing missing in their observations should occur near the entrance sill and/or at the sloping boundaries of the deep basin. This conclusion is supported by recent microstructure measurements in the Gullmar Fjord by Arneborg et al. (2004a).

It thus seems that most of the vertical mixing in the basin water of fjords is executed close to the bottom boundary. This seems to be the case also in lakes. Tracer experiments were done in the 1990s in Lake Alpnach (central Switzerland). Like the tracer experiment in the Oslo Fjord and other fjords, these experiments showed that most (about 90%) of the vertical mixing is executed close to the bottom boundary (Goudsmit et al., 1997).

Exchange of basin water

The residence time T_e of the basin water below sill level may depend on the following three factors: the spectral distribution of the temporal density variability of the coastal water, the rate of diapycnal mixing of the basin water, and the time T_{fill} it takes to fill the basin with new deepwater. The latter is determined by the transport capacity of the mouth and the volume of the basin water. The two-layer transport capacity of a strait was investigated by Stommel and Farmer (1953), see Section “[Estuarine Circulation](#)” above. The present author investigated how barotropic fluctuations could increase the transport capacity of a strait with respect to exchange of two water masses (Stigebrandt, 1977). Farmer and Armi (1986) investigated the control of two-layer transport through horizontal and vertical constrictions in the presence of barotropic fluctuations.

A model calculating T_e and the mean density of the basin water was developed by Stigebrandt and Erlandsson (2006). In the model, see [Figure 9](#), the water exchange is driven by horizontal density differences between the fjord and the offshore area above sill level, i.e., by intermediary circulation as described in Section “[A Simple Empirical Model of Intermediary Circulation](#).” The residence time of the basin water is divided in periods of filling and stagnation in the basin water and the lengths of those periods was identified from the model results. The model requires that the variability of the offshore density field, ρ_{in} , is resolved in spectral bands and that the rate of vertical mixing in the basin water is known.

The rate of mean density reduction in the basin water due to diapycnal mixing can be written as (Aure and Stigebrandt, 1990):

$$\frac{d\bar{\rho}}{dt} = -\frac{C_W W}{gH_b^2} \quad (55)$$

Here $W = P_B/At$ where is defined by [Equation 51](#) and At is the horizontal surface area of the fjord at sill level, C_W is an empirical nondimensional constant (≈ 2), g the

Hydrodynamics and Circulation of Fjords, Figure 9 Vertical cross section through a fjord describing the physical transports during stagnant periods of the basin water (*solid lines*) and during basin water renewals (*dashed lines*). Q_f is the freshwater input, Q_i is the intermediary exchange between the coastal water and the fjord, and Q_e is the turbulent exchange flow between the basin water and the water above sill depth.

acceleration of gravity and H_b the mean thickness of the basin water. For model computations, Stigebrandt and Erlandsson (2006) described the effect of diapycnal mixing as a two-way exchange Q_e that they derived from [Equations 51](#) and [Equations 55](#), thus

$$Q_e = \frac{2Rf(P_T + P_W)}{g(\bar{\rho} - \bar{\rho}_1)H_b} \quad (56)$$

To keep the model as simple as possible, density is considered to be a function of only salinity, and the equation of state in [Equation 20](#) is used. In addition, the freshwater supply is turned off, i.e., $Q_f = 0$. The response of the spatial mean salinity S of the basin water, of volume V_b , to inflow of new deepwater of salinity S_{in} and to vertical mixing with the upper layer of salinity S_1 is described by the following equation:

$$\frac{dS}{dt} = \varepsilon \frac{Q_{\text{in}}}{V_b} (S_{\text{in}} - S) + \varepsilon_1 \frac{Q_e}{V_b} (S_1 - S) \quad (57)$$

For the model computations, Q_{in} is due to intermediary circulation according to [Equation 10](#).

The spatial mean salinity S_1 of the upper layer is described by the following equation:

$$\begin{aligned} \frac{dS_1}{dt} = & (1 - \varepsilon) \frac{Q_{\text{in}}}{V_1} (S_{\text{in}} - S_1) + \varepsilon_1 \frac{Q_e}{V_1} (S - S_1) \\ & + \varepsilon \frac{Q_{\text{in}}}{V_1} (S - S_1) \end{aligned}$$

Here the volume of the upper (lower) layer is V_1 (V_b). The switch functions ε and ε_1 are defined as follows; ε equals 1 if $S_{\text{in}} > S$ and 0 otherwise; ε_1 equals 1 if $S_1 < S$ and 0 otherwise.

The model was run for two cases with different forcing of the intermediary flow. The variability of ρ_{in} was partitioned into periods of 1 week, 1 month, 1 year, and 7 years. In Case 1, the percentage contributions to the

variability from the different period bands were (18,18,52,12) and in Case 2 the long-term component was turned off and the variability was described by (22,22,56,0). The total variability was the same in the two cases.

Figure 10 shows that the fjord with the weakest mixing is stagnant for several years in Case 1. This is due to combination of weak mixing rate and appreciable variation of the external density field on the timescale of several years. If the mixing rate increases, the length of the stagnation periods decreases, cf. case (c) and (d) in Figure 10. If the long-term variability is turned off (Case 2), the frequency of water exchange increases drastically, in the fjord with the weakest mixing, Figure 11. However, there are still

some years that lack water exchange due to the variability induced by higher frequencies.

From their model runs Stigebrandt and Erlandsson (2006) identified two different classes of systems. *Mixing systems* have short T_{fill} and T_e depends on the rate of diapycnal mixing in the basin water and on the spectral distribution of the density variability in the coastal water. Long-period variations in the offshore density field (e.g., the North Atlantic Oscillation with a period of several years) may determine T_e if the mixing in the basin water is weak. *Transport systems* have long T_{fill} and T_e is determined by the baroclinic transport capacity of the mouth. Such systems are “over mixed,” which means that increasing the rate of vertical mixing of the basin water will have

Hydrodynamics and Circulation of Fjords, Figure 10 Results of a 30-year-long simulation for Case 1. (a) The top panel shows the variations of density at sill level in the coastal water. The three panels (b–d) show periods of stagnation (white) and periods of exchange (black) of the basin water for three different values of mixing rates (dp/dt) (-0.0001 , 0.0005 , -0.0010) ($\text{kg m}^{-3} \text{ day}^{-1}$) with increasing rates from left to right.

Hydrodynamics and Circulation of Fjords, Figure 11 The same conditions as described in Figure 10 except for the water exchange with the sea which is according to Case 2.

no effect on T_e , cf. Stommel and Farmer (1953). If the locally supplied freshwater is turned off, i.e., $Q_F = 0$, the temporal and spatial mean density of the basin water was shown to equal the offshore temporal mean density at sill level and T_e equals two times T_{fill} in that case. The Baltic proper is a good example of a transport system with strong barotropic currents usually overriding the baroclinic currents in the mouth.

In the model described above, new basin water is not mixed with the old basin water which it is in real systems. New basin water flows along the bottom as a dense bottom current which entrains old basin water on its way to greater depths. Thereby the new deepwater will be a mixture of the old basin water and the new water flowing across the mouth. A simple model of an entraining dense bottom current was described in Stigebrandt (1987). Entrainment into dense bottom currents in fjords has been described by Liungman et al. (2001) and Arneborg et al. (2004b). The dynamics of entraining dense bottom currents was studied experimentally and theoretically by Umlauf and Arneborg (2009a, 2009b).

Wind drift and related phenomena

The relative effects of wind, tide, and river runoff on the circulation of the surface layer of a small fjord were investigated by Buckley and Pond (1976) using drogues that were tracked with radar for several days. They found that wind forcing was dominant. River runoff was also important since it caused large horizontal shears in the flow. Tidal effects were negligible. Due to a strong pycnocline, the surface layer appeared to be nearly decoupled from the underlying water. This is in line with the concept slippery sea due to almost laminar flow conditions between the surface layer and the underlying water (Houghton and Woods, 1969). Stacey (1999) demonstrated that a numerical model could simulate the near surface wind-forced currents in Knight Inlet quite well.

Fluctuating winds along the axis of a fjord may generate both surface and internal seiches (standing long waves). Well developed fundamental mode surface seiches occur in the Gullmar Fjord. The seiches occur also when the fjord is covered by land-fast ice which shows that they can be generated remotely by rapid changes of the pressure field outside the mouth of the fjord, e.g., Parsmar and Stigebrandt (1997). These authors showed that the surface seiche in the Gullmar Fjord is dampened by the generation of internal waves at the sill with the same frequency as the seiche by the mechanism described in Section “[Generation of Internal Tides and Tidal Jets at Sills](#).” These internal waves contribute about 25% of the energy for turbulence and mixing in the basin water of the fjord. Gullmar Fjord also has large internal seiches generated by both local wind and waves in the coastal stratification see Arneborg and Liljebladh (2001a). In a companion paper they show that internal seiches contribute about 35% and internal tides about 40% of the energy available for turbulence and mixing in the basin water (Arneborg and Liljebladh, 2001b). However, since variability in the

coastal water (Section [Intermediary Circulation Forced by Density Variations in the Coastal Water](#)) apparently contributes to generation of both surface and internal seiches, it might be fair to estimate that the local wind contributes 30%, the variability of the coastal density field 30% and tides 40% of the energy available for turbulence in the basin water of Gullmar Fjord.

Hydrodynamics of fjords applied to fish farming

In many practical applications, it is important to know the current conditions in a certain location of a fjord. One example is aquaculture where it is necessary to estimate the carrying capacity which is the largest possible biomass of the cultured species that can be grown in a certain location without unacceptable effects on the environment and on the farmed stock. The carrying capacity may be estimated from several simultaneously valid criteria, all giving different estimates. The lowest of these then defines the carrying capacity, see e.g., Stigebrandt (2011) and Tett et al. (2011) for overviews and models.

For fish farming in cages, the current flushing the cages is very important since it brings oxygen to the fish and at the same time removes dissolved wastes produced by the fish. Since the fish might be seriously hurt if the oxygen concentration in the cages becomes lower than a certain value (different for different species), it is of utmost importance to know the minimum flushing rate of the cages which occurs in periods of minimum current speed. Particulate waste, i.e., feces and non-eaten feed, sink through the bottom of the cages. Before reaching the sea bed it will be dispersed by time-varying currents. Current variability is thus an important factor in determining the specific loading of the bottom with organic matter. Organic matter that reaches the seabed will feed benthic animals. However, if the oxygen demand to decompose the organic matter that reaches the sea bed is greater than the supply of oxygen, anoxic conditions may develop below the fish farm meaning that animals may not live there and the organic waste from the farm will be decomposed by anaerobic processes producing hydrogen sulfide and methane. It is thus necessary to know the minimum transport of oxygen to the bottom in order to estimate the largest flux of organic matter that allows living benthic animals beneath the farm in periods of weak currents. The current properties described here are necessary to know to compute the carrying capacity of a certain farmed species at a certain location. There may be other current properties, connected to the horizontal spreading of infectious diseases and sea lice between farms, that also are important to know before farms are established. Of course, there may be other human needs to know additional current conditions in fjords, not mentioned in this entry.

Summary

Fjords provide excellent environments for studies of several hydrodynamic processes. The upper layers of many

fjords have baroclinic estuarine circulation, internally driven by local freshwater supply and wind mixing. The amount of freshwater in the surface layer may be hydraulically controlled by the topography of the mouth. Topography is also important for tidal circulation and for generation of internal tides and jets and topography may isolate basins by preventing water exchange with neighboring basins and with the coastal area. Exchange of water in isolated basins, below sills, is driven by diapycnal mixing that decreases the density. Turbulence in sill basins usually gets most of its power from tides via internal tides and jets. Externally forced baroclinic circulation, driven by temporal variations of the vertical density distribution in the coastal water outside fjords, is usually much larger than the internally forced estuarine circulation. The understanding of important hydrodynamic fjord processes and internally and externally forced circulation modes of fjords and isolated deep fjord basins is reviewed using observations and simple dynamical models. It is finally shown that knowledge of many properties of fjord circulation is necessary to determine the carrying capacity of localities in fjords for fish farming.

Acknowledgments

Malin Ödalen analyzed data from Lista, obtained from Institute of Marine Research, Bergen, Norway. Bengt Liljebladh put out and recovered the CTD-chain and ADCP mooring at Oscarsborg in the Oslo fjord and made the plot in Figure 6. This work was supported by the Institute of Marine Research, Bergen, Norway.

HYDRODYNAMICS OF VERY SHALLOW LAKES

Lars Bengtsson
 Department of Water Resources Engineering, Lund
 University, Lund, Sweden

Introduction

Very shallow lakes, being shallow all over, are special compared to lakes that are deep at some places in that they are so much influenced by bottom processes and near-shore processes. These lakes are only few meters deep and are well mixed in the vertical. Only during daytime the surface water temperature may slightly differ from the bottom water temperature. Wind-induced waves cause bottom material from almost the entire lake bottom to resuspend during strong winds. Vegetation progresses from the shores into the lake and there may be patches with reeds or submerged vegetation also in the middle of such a lake. A small lake level drop results in rather large decrease of the lake volume, which together with resuspension of bottom material may result in large increases of the concentration of different constituents. Resuspension brings nutrients from the sediments to the water, but also reduces the penetration of solar radiation.

The water in a very shallow lake is forced to move from direct wind impact, wind-induced circulation, from the

setup of the water surface and the consequent forth-back movement, when the wind ceases to blow, i.e., seiche currents, and from nonuniform heating of the water surface when the heat exchange is different within vegetation belts and on open water, which induces large-scale convective motions.

Wind-induced circulation

The currents in a shallow lake are primarily driven by the wind. However, there is no wind stress within the reed vegetation and there are sheltered areas behind the vegetation in the open lake. When the wind is strong, there is complete mixing from surface to bottom and the current is in the same direction over the whole depth. With no or little vegetation the circulation tends to be such that the currents are in the wind direction along the shores but against the wind in the middle of the lake, which is very different from deeper lakes, where the return current is at greater depth. The surface currents are of the order 1% of the wind speed or less, but the circulation is much affected by the distribution of the vegetation and can be quite complex with many gyres as is found from many Hungarian studies. Wind-driven currents have been extensively studied in Hungarian lakes from field observation, physical model studies, and mathematical models, e.g., Josza (2006). The return currents against the wind tend to be much within reed belts, where there is no direct stress from the wind on the water surface. Also nonuniform wind stress due to wind protection of the shores induces gyres and complex circulation pattern, e.g., Podsechine et al. (1999).

Seiche currents

The setup of the water surface is very minor, of the order mm/km in most lakes, but it is inversely related to the water depth, so it is more in shallow than deep lakes, see the entry [Circulation Processes in Lakes](#). The speed of the seiche moving back and forth along the lake is that of a gravity wave. When the water is moving back and forth there is exchange of water from the open water into nearshore reed belts. The process is, however, poorly quantified.

Water exchange between vegetation belts and open water

Differential heating of surface waters within vegetation belts and open water induces convective large-scale currents between the nearshore water and the open lake. In daytime the water within the vegetation is shaded from solar radiation and in nighttime the vegetation reduces the back radiation to the atmosphere. In daytime the water in the open lake tends to be warmer than the water within the vegetation, which results in a current system with surface water flowing into the vegetation and a compensating outward movement near the bottom, as is illustrated in [Figure 1](#). In nighttime the current system is the reverse. In Lake Kranke in the very south of Sweden up to 1°C

temperature difference has been observed and currents of 1.5 cm/s, Borell-Lövstedt and Bengtsson (2008a). Similar current systems due to differential heating develop between bays and open deeper waters in a lake, MacIntyre et al. (2002).

Waves

Waves in shallow lakes are small and short and reach full height already after short duration. It seems they can be well predicted with empirical fetch limited deep water wave forecasting equations developed for the ocean. The waves are damped, when passing through vegetation or

Hydrodynamics of Very Shallow Lakes, Figure 1 Water exchange between open water and vegetation belt during a sunny day.

over submerged vegetation. In Lake Kranke the waves are damped about 50% after traveling through 10 m reed of density about 40 m^{-2} when the average stem diameter is about 4 mm. Studies on coastal sea grass show about the same or less damping with higher waves than those in a small lake. The wave height, H , downstream the vegetation can be determined (reduced from H_0 upstream the vegetation) by an equation like, see Borell-Lövstedt and Larson (2010),

$$H = H_0 / (1 + ND F C_d x)$$

where N is reed stem density, D is the stem diameter, C_d is drag coefficient, and where F is a function of wave characteristics (period, length, and height) and of water depth. It is seen that the damping effect as per meter is reduced through the reed belt along x . The effect of the concentration of reeds is large. Doubling ND means an approximate double reduction of the wave height over 10 m.

Resuspension

In a very shallow lake there are no accumulation bottoms. Material brought in suspension accumulates all over the lake and can be resuspended at every storm occasion. However, sediments within vegetation may accumulate until a severe storm comes from special directions. Since material is settled all over the lake bottom the sediments are not sorted. Erosion of bottoms may be due to inflowing rivers or large bottom currents, but are almost always caused by wind-induced wave action. Bottom material is

Hydrodynamics of Very Shallow Lakes, Figure 2 Accumulation and frequent resuspension bottoms in Lake Kranke.

eroded, when the shear at the bottom exceeds a threshold value. The erosion rate, E , is determined as

$$E = C_e(\tau/\tau_c - 1)$$

where C_e is a coefficient, which depends on the character of the sediments, τ is the bottom shear, and τ_c is the critical shear stress. However, the source of erodable material for a given shear stress is limited. After not very long storm duration all this material is brought in suspension. The amount of material brought in suspension is the net entrainment depth times the erodable lake bottom area. The entrainment, e , is related to τ/τ_c just as the erosion rate is. Lick (1982) suggested an exponent of $b = 2$ in the expression

$$e = C_n(\tau/\tau_c - 1)^b$$

where C_n is a coefficient which is related to how consolidated the sediments are, i.e., related to the time between storms. The concentration of suspended matter is e/h added to the background concentration with h as the mean water depth. The concentration of suspended matter is higher in very shallow lakes than in deeper lakes.

Over most lakes there are prevailing wind directions. Loose material eroded during the action of these winds settle all over a shallow lake, but may remain within the vegetation on the leeward shores from which the wind is coming. The soft sediments are thicker here than on the rest of the lake, until a strong wind is blowing from the opposite direction, as is illustrated in Figure 2. Then the thick material accumulated within the vegetation is brought in suspension resulting in high concentration of suspended matter. Sediment distribution depending on prevailing wind directions has been found in Lake Vörtsjärv (Nöges et al., 1999) and Lake Kranke (Borell-Lövstedt and Bengtsson, 2008b). In Lake Kranke shifts from clearwater to turbid state can be related to strong winds from uncommon direction.

HYDROLOGICAL SIZING OF WATER SUPPLY RESERVOIRS

Adebayo J. Adeloye

School of the Built Environment, Heriot-Watt University, Edinburgh, Scotland, UK

Introduction

Surface water resources in lakes, rivers, and artificial reservoirs constitute a vital component of water supply systems in most countries. In particular where rainfall and hence river flows are seasonal, reservoirs are required to regulate the water available for use by storing the water during the period of excess rainfall for release during the period of low or no rainfall. A reservoir, therefore, helps to minimize the temporal variability in the pattern of water

available for use for various purposes including domestic and industrial water supply, irrigation, and in-stream needs, such as water quality enhancement and water pollution control.

To be able to obtain the most out of a reservoir development, the dam must be appropriately sized such that, given the record of inflow at the site, it is able to meet its target demand with an acceptable level of performance. In other words, the reservoir-sizing problem can be thought of as the development of a relationship of the form:

$$K_a = f(Q, D, R) \quad (1)$$

where K_a is the reservoir capacity (or size); D is the outflow (which is a generic term for the demand and other inevitable sinks of water such as evaporation and seepage); Q is the inflow at the reservoir site; R is the level of performance; and $f(\cdot)$ is a functional form.

The functional form in Equation 1 is complex and, except for highly simplified, albeit unrealistic, systems, has no closed form solution. A more practical approach has been to use empiricism; consequently most of the available reservoir-sizing techniques have been based on such empiricism. The aim of this essay is to give a brief yet sufficient outline of the most commonly used empirical methods. In selecting the methods to present, emphasis was placed on ease of use and data requirements. Thus, methods which are readily usable and which are not too demanding in terms of their requirements will be emphasized because such are amenable to be applied in ungauged or sparsely gauged catchments prevalent in less developed economies where exercises in reservoir planning are still common. In more developed economies, current concerns are with better operational management of existing facilities rather than the development of new resources. For readers interested in the more analytically rigorous planning methods and operational tools, reference can be made to McMahon and Adeloeye (2005). Meanwhile, some basic definitions of the commonly used terminologies in the reservoir-sizing problem will be given.

Reservoir sizing terminologies

Storage, S_t

This is the volume of water stored in a reservoir at a given time and used for meeting the various demands placed on the reservoir. The storage, therefore, defines the state of the reservoir at any time, t . More specifically, the storage is often referred to as the active storage, to distinguish it from the dead storage and flood surcharge storage (see Figure 1). In the reservoir-sizing problem, S_t is regarded as a state variable with the upper limit equal to the capacity of the reservoir, K_a . Off-take of water from the reservoir for the purpose of meeting demand is normally made above the dead storage because of the poor quality of water stored in the latter.

Hydrological Sizing of Water Supply Reservoirs,
Figure 1 Storage zones in a water supply reservoir.

Inflow, Q_t

This is the total amount of water flowing into the reservoir in a given time period. The inflow is dominated by the run-off at the catchment outfall, but other sources of water might include direct rainfall on the reservoir surface, diversions from other sources such as through inter-basin transfers, and releases from an upstream reservoir or group of reservoirs.

Demand, D_t

This is the amount of water required from the reservoir in a given period. Other terms used synonymously with the demand are the draft, release, and yield. However, in a strict sense, the demand is different from these other terms in the sense that while the demand might be a fixed quantity, the three latter terms define a variable quantity whose value depends on the way the reservoir is operated. Thus, depending on the state of the reservoir storage, S_t , and the anticipated inflow, the release might be equal to, lesser, or greater than the demand.

Critical period

The critical period is the period of low inflow sequence into a reservoir during which if the reservoir was full at the beginning, it will be empty at the end of the period. The majority of reservoir-sizing techniques are based on the critical period concept because, in reality, any supplementary water provision for the purpose of meeting the demand should only be required over the critical period. For all other periods, the natural river flow is sufficient to meet the demand, and there is therefore no need to store water for release during such periods.

Within-year and over-year storage size

Within-year storage is that required to meet seasonal disparity between inflow and demand, whereas over-year storage is that required for meeting the disparity over several years. The distinction between these two types of storage requirements is important because they require different temporal scale of data to adequately analyze.

Hydrological Sizing of Water Supply Reservoirs, Figure 2 Schematic illustration of a reservoir storage-yield (s-y) function highlighting the effect of annual flow variability.

For example, Figure 2a and b is schematics of a reservoir storage-yield (s-y) function in which both the yield and storage size have been scaled by the mean annual runoff to remove the effect of river size. For low annual variable rivers (i.e., rivers with $C_v < 0.35$, where the C_v is the coefficient of variation of annual runoff and is estimated as the standard deviation of annual runoff divided by its mean), there is significant, additional within-year storage to meet demands in dry months. On the contrary, within-year requirements are minimal in high annual variable rivers (see Figure 2a), and the storage-yield function for such rivers can be developed using annual runoff data; seasonal or monthly runoff data must be used to develop the function for low annual variable rivers to minimize undersizing of the reservoir.

Reservoir performance measures

A reservoir is said to perform satisfactorily if it meets the demand in all time periods; when this is not the case, there is a performance failure. Reservoir performance is traditionally characterized by the *reliability*, *vulnerability*, and *resilience*.

Reliability: The reliability concept can be applied in either the time or volume domain.

Time-domain reliability – This is the proportion of the total time under consideration in which a reservoir will be able to meet the demand without shortage. A general expression for computing time-domain reliability, R_t , is:

$$R_t = \frac{N_s}{N} \quad (2)$$

where N_s is the total number of intervals during which the demand was met and N is the total number of time intervals under consideration. Where annual data are used in the analysis, then N_s becomes the number of successful years and N becomes the number of years in the

simulation period, and the estimated reliability is termed the *occurrence-based reliability* because it represents the average probability of achieving the particular yield in any given year (Klemes et al., 1981) or conversely, the average recurrence interval for the yield, similar to average recurrence intervals used in the study of floods. For time intervals less than the annual, e.g., monthly, the time-based reliability is generally higher than the annual occurrence-based reliability.

The complement of the reliability is the frequency of failure, F , i.e.,:

$$F = 1 - R_t \quad (3)$$

Volumetric-domain reliability – The volumetric reliability, R_v , is calculated as the total quantity of water actually supplied divided by the total quantity of water demanded during the entire operational period, i.e.,:

$$R_v = \frac{\sum_{t=1}^N D'_t}{\sum_{t=1}^N D_t} \quad (4)$$

where D'_t is the actual supply from reservoir system during period t and D_t is the demand during the same period. If the demand is satisfied in all the time periods, then $D'_t = D_t$ for all t and R_v is unity.

Let us investigate the relationship between the relative magnitudes of R_t and R_v . Consider a single failure in the total period N during which the period demand is D_t as usual. The supply during this failure period is, using our usual notation, D'_t where $D'_t < D_t$

Therefore,

$$\text{failure frequency} = \frac{1}{N}$$

and

$$\text{volumetric failure} = \frac{D_t - D'_t}{D_t N} = \frac{1}{N} - \left(\frac{D'_t}{D_t} \right) \frac{1}{N}$$

Thus, unless $D'_t = 0$, i.e., no supply at all during the single failure period, the volumetric failure will always be lower than the occurrence-based failure for any reservoir system that manages to supply some water during failure periods, i.e., $R_v \geq R_t$. The question then arises as to which of the two, time-based or volume-based, to use for planning decision-making. A general advice is to base the initial decision on the time-based reliability while at the same time computing the volumetric reliability. Observations on this volumetric reliability may then be made to adjust further the time-based reliability, e.g., the time-based reliability may be relaxed if the volumetric reliability is very high or made more stringent if the volumetric reliability is too low.

Resilience: The most widely used definition of resilience is by Hashimoto et al. (1982) who defined resilience as the probability that a reservoir system will recover following a failure:

$$\varphi = \frac{1}{\left(\frac{f_d}{f_s} \right)} = \frac{f_s}{f_d}; \quad 0 < \varphi \leq 1 \quad (5)$$

where φ is resilience, f_s is number of continuous sequences of failure periods, and f_d is the total duration of the failures, i.e., $f_d = N - N_s$. Since the denominator $\left(\frac{f_d}{f_s} \right)$ on the right-hand side of Equation 5 is the average duration of continuous failure periods, then the resilience is the reciprocal of the average duration of failure periods. Thus, the longer the average duration of continuous failure periods, either due to a longer f_d or a fewer f_s , the smaller is the resilience and hence the more difficult it is for the reservoir to recover from failure.

Another measure of resilience, which is much easier to estimate than the measure in Equation 5, was recently suggested by McMahon et al. (2006):

$$\varphi = \frac{\bar{D}'}{D} \quad (6)$$

where $\bar{D}'$ is the minimum period release by the reservoir.

Vulnerability: A reservoir performance measure allied to the volume-based reliability is the vulnerability or the impact of failure. Hashimoto et al. (1982) defined vulnerability as the average of the maximum shortfalls occurring in each of the continuous failure periods, i.e.,:

$$\eta' = \frac{\sum_{k=1}^{f_s} \max_{t \in k} (D_t - D'_t)}{f_s} \quad (7)$$

where η' is vulnerability, $\max(\cdot)$ is maximum shortfall during the k th continuous failure sequence, and f_s is the

number of continuous failure sequences in the simulation. A more useful form is the dimensionless vulnerability η , given by:

$$\eta = \frac{\eta'}{D} \quad (8)$$

McMahon et al. (2006) investigated the relationship and possible trade-offs between various measures of reservoir performance using extensive Monte Carlo simulation. They found out that the resilience and dimensionless vulnerability are complementary, i.e.,:

$$\varphi \cong 1 - \eta \quad (9)$$

implying that once one of them is evaluated, the other can be easily inferred. Equation 9 can readily be established if the alternative definition of resilience in Equation 6 is combined with Equations 7–8 (see McMahon et al. (2006) for details).

Other performance indices: a summary

Other performance indices have recently appeared in the literature; the overriding aim of these indices is the derivation of a single index, which will incorporate the combined effects of some of the indices described above (Loucks, 1997). Simonovic (1998) called such integral indices the *figures of merit* (FM), and examples of these are the *drought risk index* (DRI) (Zxongue et al., 1998) and the sustainability index (Loucks, 1997). The DRI is defined as:

$$\kappa = \varepsilon_1(1 - R_t) + \varepsilon_2(1 - \varphi) + \varepsilon_3\eta \quad (10)$$

in which ε_1 , ε_2 , and ε_3 ($\sum_{i=1}^3 \varepsilon_i = 1.0$) are weights that may

be assigned values depending on the relative significance placed by the analyst on each of the three performance indices. If the three indices are weighted equally, then $\varepsilon_1 = \varepsilon_2 = \varepsilon_3 = 1/3$. Where the vulnerability is the overriding consideration, then more weight can be given to ε_3 relative to the other two weights. The problem with the use of the DRI is that the choice of the weights is subjective.

The sustainability index was defined by Loucks (1997) as:

$$\lambda = R_t\varphi(1 - \eta) \quad (11)$$

where λ is sustainability. The use of multiplication in Equation 11 serves a similar purpose to the weights used in DRI in that it gives an added weight to the statistical measure having the lowest value (Loucks, 1997). For example, if any of these measures are zero, the other indices essentially become irrelevant. Equation 11 is intuitively correct because the sustainability of a reservoir system increases the greater the reliability and resilience, and the smaller the vulnerability. However, although

Equation 11 provides a quantitative measure of sustainability, it is still largely untested with regard to reservoir design and management; other more descriptive sustainability criteria such as fairness, reversibility (of impacts), risk, and consensus (Simonovic, 1998) are still preferred despite their subjectivity.

Methods for hydrological reservoir sizing

The methods to be described can be classified into two broad types: quick or generalized methods and the sequential methods.

Quick (or generalized) methods

The quick methods are fast, back-of-the-envelope methods whose distinguishing characteristic is that they do not require the sequential analysis of complete time series data of inflow to the reservoir. For most of the techniques in this category, only some statistics of the inflow, such as the mean, the coefficient of variation, and the lag-1 serial correlation coefficient, are required as input, in addition to an assumption about the probability distribution function of the inflow.

Dincer procedure

One of the simplest algorithms to size a single reservoir was developed by Dincer (see McMahon and Adeloye, 2005). Dincer assumed a sequence of annual independent inflows with a mean, μ , and standard deviation, σ , and showed that if the annual flows have a normal distribution, then the duration of the critical period (years) is:

$$n_{\text{crit}} = \frac{z_F^2}{4 \left(1 - \frac{D}{\mu}\right)^2} C_v^2; \quad D < \mu \quad (12)$$

and the capacity is:

$$K_a = \frac{z_F^2}{4 \left(1 - \frac{D}{\mu}\right)} \frac{\sigma^2}{\mu}; \quad D < \mu \quad (13)$$

where z_F is the standard normal variate with F probability of non-exceedance, i.e., K_a is the capacity with a probability 100 $F\%$ of running dry (failing) in any year, where F is the failure frequency given by Equation 3. For a known F , the corresponding z_F is tabulated in most standard textbooks on statistics. Alternatively, z_F can be approximated using (Stedinger et al., 1993):

$$z_F = \frac{F^{0.135} - (1 - F)^{0.135}}{0.1975} \quad (14)$$

Where the annual flows are log-normally distributed, the Dincer model can still be used if the parameters μ and σ are replaced by those of a log-normal distribution (as described by McMahon and Adeloye, 2005).

Gould gamma method

For annual flows distributed as gamma, z_F should be transformed to the equivalent gamma variate, g_F , using:

$$g_F = \frac{2}{\gamma} \left[\left\{ 1 + \frac{\gamma}{6} \left(z_F - \frac{\gamma}{6} \right) \right\}^3 - 1 \right] \quad (15)$$

where γ is the sample skew coefficient for the annual flows. For a gamma distribution, $\gamma = 2C_v$. McMahon and Adeloye (2005) contain simplified algorithms for estimating from time series data γ and the other summary statistics required by the Dincer and Gould gamma methods. Furthermore, all the required flow statistics can be obtained easily using Microsoft Excel™.

However, both the Dincer and Gould gamma methods have their limitations. Firstly, by using annual flow statistics, they can only estimate the over-year storage; where within year requirements are significant, an adjustment must be made. Adeloye et al. (2003) and Adeloye and De Munari (2006) have developed techniques for carrying out the adjustment. Other limitations of the two quick methods are:

- Neglect of serial correlation in the annual flows
- Neglect of evaporation and other secondary processes

Nonetheless, the techniques are very rapid and useful during preliminary reservoir evaluation studies. Besides, because of their minimal information requirement, i.e., mainly the mean and CV of annual flows, the techniques are potentially applicable at ungauged sites as demonstrated by Adeloye et al. (2003), who also presented procedures for estimating these parameters at ungauged sites.

As remarked before, the Dincer and Gould gamma techniques belong to a broad range of methods known as the generalized storage-yield models. However, while there are other examples of such models – see for example Vogel and Stedinger, 1987; Bayazit and Bulu, 1991; Buchberger and Maidment, 1989; Adeloye and De Munari, 2006 – these two are the easiest to apply, and their estimates can easily be adjusted for within-year requirements as described by Adeloye et al. (2003). Consequently, further details about the other generalized models will not be provided in this report; however, for those interested, additional information is provided by McMahon and Adeloye (2005).

Sequential methods

The procedures presented earlier do not require the sequential analysis of time series data to obtain the storage size. However, except during preliminary planning analysis or when the site of interest is ungauged, most storage sizing determinations require the sequential analysis of inflow time series data. Sequential methods are better because they take into account all the intrinsic characteristics of the data record – serial dependence, variability, and probability distribution function – that affect the storage size. The downside of sequential methods is that by requiring time series data, they are precluded from being applied at ungauged or sparsely gauged sites. Some of the commonly used techniques in this category will now be described briefly.

Hydrological Sizing of Water Supply Reservoirs, Figure 3 Mass curve analysis showing the mass curve (*thick continuous line*), cumulative demand lines (*thick dash line* whose slope = demand per period), and two possible critical periods (a–b, d–e). The maximum difference of 451 MCM is the reservoir size and occurs during the critical period a–c. (Adapted from McMahon and Adeloye, 2005.)

The mass curve procedure

The mass curve procedure was developed by Rippl (1883) and has been used to size reservoirs in many parts of the world over the past century. The method estimates the reservoir capacity as the maximum difference between the accumulated demand and accumulated inflow (or mass curve) during a critical low flow sequence in the historic runoff record at the reservoir site. An example of the mass curve is shown in Figure 3, which also illustrates the concept of the critical period and the determination of the reservoir capacity given the demand. Further information about the step-by-step procedure of constructing the mass curve is provided by McMahon and Adeloye (2005).

The mass curve designs for the worst historic critical drought sequence; if a severer drought occurs during future operational period of the reservoir, the sized reservoir may not meet the demand. This is the biggest limitation of the mass curve approach, i.e., it does not allow the risk of failure to meet the demand to be explicitly evaluated during the design stage.

Other limitations of the mass curve include inability to explicitly accommodate secondary processes effects, e.g., evaporation and seepage, and seasonality in demand, all of which may mean that the reservoir is undersized. The inability to accommodate seasonality in demand stems from the graphical nature of the mass curve which requires that the cumulative demand line must be straight, i.e., a constant demand per period (see Figure 3). Nonetheless, the mass curve is still a very popular method, and the fact that it is graphical means it offers a powerful way of

visualizing the behavior of the reservoir in terms of its filling, emptying, and spilling. In Figure 3, the reservoir is full at “o,” spilling between “o and a,” empty at “b,” full again at “c,” and spilling between “c and d.” Finally, the mass curve can also be used to determine the yield if the capacity is known as described by McMahon and Adeloye (2005).

Sequent peak algorithm (SPA)

The SPA was developed by Thomas and Burden (1963) as the numerical version of the graphical mass curve. The original formulation is described by McMahon and Mein (1986); however, a more easily implemented formulation described by Lele (1987) (see also McMahon and Adeloye, 2005) will be presented here.

In its basic form, the SPA technique estimates the storage size for a failure-free operation of an initially full reservoir over the historical record, i.e., for 100% reliability over the N -year period.

Let:

- C_t be the cumulative sequential deficit at the beginning of period t in a record of N periods
- C_{t+1} be the corresponding deficit at the end of t , i.e., at the beginning of $t + 1$
- D_t be the demand in period t and Q_t be the inflow during t

Then the SPA is implemented in the following steps:

Step 1. Set $C_0 = 0.0$, i.e., assume that the initial deficit is zero, in other words that the reservoir is initially full. (Note: This assumption is common to all critical period

techniques although it is not a problem with the SPA because if it is wrong, it will become apparent during the SPA solution of the problem.)

Step 2. For $t = 1, 2, \dots, N$, calculate:

$$C_{t+1} = \max\{0.0, (C_t + D_t - Q_t)\}$$

Step 3. If $C_{N+1} = C_0$, then go to step 4; else if this is the first iteration, then set $C_0 = C_{N+1}$ and go to Step 2; else STOP: the SPA has failed because gross demand is higher than the average inflow.

Step 4. Estimate reservoir size $K_a = \max(C_{t+1})$ all over $t = 1, 2, \dots, N$.

An example implementation of the SPA is shown in Table 1 for a 15-period inflow sequence (see the second column of Table 1). The constant demand per period is 4.5 units (shown in the third column), and the calculated sequential deficits are shown in the fourth column. The estimated reservoir size is 11 units, which is the maximum of the entries in the sequential deficits column.

The SPA is easy to implement, but although it removes the need to draw a graph and can be used to analyze seasonality in demands and inflows, the technique still suffers from similar limitations of the mass curve technique. Attempts have been made to extend the SPA so that it can design for any desired reliability (instead of the implicit no-failure reliability over the historic record), accommodate evaporation and rainfall fluxes, and analyze multiple reservoirs. Details of the extended SPA are relatively complex and will not be presented in this report; however, for those interested, the necessary details are available elsewhere (see Lele, 1987; Adeloye et al., 2001; Montaseri and Adeloye, 1999; McMahon and Adeloye, 2005).

Behavior analysis

As the name implies, behavior analysis (BA) simulates the behavior of the reservoir taking into account the inflow,

Hydrological Sizing of Water Supply Reservoirs, Table 1
Implementation of the SPA

t	Q_t	D_t	$C_{t+1} = \max\{0.0, (C_t + D_t - Q_t)\}$
0			0
1	5	4.5	0.0

15 = N	9	4.5	0.0 ($C_{N+1} = 0.0$); hence no need for repeating the data record

releases (including secondary processes such as evaporation and direct rainfall), and operating policy for the reservoir. Unlike the methods described previously, which can only handle simple, single reservoir configurations, behavior analysis can handle any multiple reservoir configurations, no matter how complex. BA is perhaps the only reservoir sizing method that considers performance measures other than the time-based reliability such as the volumetric reliability, resilience, vulnerability, etc. Consequently, behavior analysis has been described as the most versatile of all reservoir sizing techniques.

BA is based on the water balance of inputs and outputs from storage as follows:

$$S_{t+1} = S_t + Q_t - D'_t - e_t A_t - L_t; \quad 0 \leq S_{t+1} \leq K_a \quad (16)$$

where S_{t+1} and S_t are the contents of the storage at times $t + 1$ and t , respectively, Q_t is the inflow to the storage during time t , D'_t is the release in volume units during time t , e_t is the net evaporation loss during time t , A_t is the surface area of net evaporation at time t , L_t is the seepage loss in volume units during time t , and K_a is the active capacity of the storage.

The constraint on the RHS of Equation 16 is important because it implies that the storage state S_t of the reservoir cannot be negative or greater than its physical size (or capacity) K_a . Unless the needed data are available, it is customary to ignore the net evaporation and other loss terms when applying Equation 16. Specifically for evaporation, McMahon and Adeloye (2005) describe methodologies for accommodating evaporation losses in a BA if the required data are available.

To use a BA to size reservoir capacity for known demand and performance index, a value for the capacity is first assumed, and the water balance equation is applied sequentially through the data record, subject to the non-negativity and capacity constraints on storage. With K_a assumed, the main decision variable is the release D'_t because its value is either sufficient to meet the demand or not. The decision on the amount of water to release and hence the value of D'_t is based on the operating policy, which in turn is dependent on the amount of water available. Whenever there is sufficient water, the demand can be met; however, when there is insufficient water, a release lower than the demand is made, and a failure performance is recorded. (Sometimes, the operating policy is not as straightforward as this and decision may be made NOT to supply the whole demand in a given period even when there is sufficient water. This is to forestall more catastrophic future failures. This practice is called *hedging*. Arriving at the decision on when and how much to hedge is complicated and beyond the purview of this entry.)

Once a decision about D'_t has been made, the state of the reservoir is then updated using Equation 16, and the analysis moves to the next time period. When the end of the data record is reached, the total number of failure occasions as well as the volume of water shortage are calculated and used to determine the performance

characteristics such as the time and volumetric reliabilities. If the performance index differs from the pre-specified target, then a new reservoir capacity is assumed, and the process is repeated until the obtained performance index is equal to the target.

In essence therefore, the sizing of a reservoir for known yield and performance using a BA is a trial and error process; consequently, the reservoir size solution of BA may not be unique. Indeed, it has been demonstrated by Adeloje et al. (2001) that this non-uniqueness occasioned by the trial and error approach in BA is a principal cause of the misbehavior of BA capacity estimates first noticed by Pretto et al. (1997).

However, BA is much more than a design or planning tool. Indeed, the most common use of BA is the assessment of the performance of reservoir systems for which the main design parameters, i.e., the demand and capacity (or size), are known. In such a situation, the analysis is no longer a trial and error procedure, and the outcome is unique information about the performance of the reservoir. If the performance is not satisfactory, then changes can be made to the design variables to achieve the desired performance.

For the above reasons, McMahon and Adeloje (2005) (see also Adeloje et al., 2001) have recommended that the use of BA be restricted to performance evaluation of existing facilities. For design purposes, the SPA described previously and its extensions (see McMahon and Adeloje, 2005) are recommended.

Sizing of reservoirs – other possibilities

The present discussion will be incomplete without outlining other possibilities for the hydrological sizing of water supply reservoirs. These include:

1. The use of stochastically generated data
2. The use of optimization (or operations research) methods
3. The use of transition probability methods

1. Stochastically generated data

All of the methods described in the earlier sections have either used single historic time series data or statistical parameters estimated from such. As adumbrated while discussing the mass curve technique, such an approach is not adequate because it fails to anticipate future droughts which could be more severe than that contained in the single historic sequence. In other words, the estimate of the capacity obtained from a historic data record is a realization of a stochastic variable, and other realizations of this variable can be obtained by analyzing other realizations of the historic record.

The generation of other realizations of the historic record uses a technique known as stochastic hydrology or Monte Carlo simulation. Without going into excessive detail, this will entail:

- Formulating a stochastic model for the inflow runoff process, e.g., for annual flow, a commonly used model is the lag-1 autoregressive (AR-1) (or Markov) model.

This is best applied if the annual flows have a normal distribution; where the flows are not normally distributed, suitable transformations, e.g., the log-normal or the Box–Cox (see McMahon and Adeloje, 2005), can be used to obtain approximate normally distributed flows.

- Calibrating the model by estimating its parameters, usually the mean, Cv, skewness, and the auto-correlation coefficient.
- Using the model to generate a large number of replicates of the historic data, with each replicate having the same length as the historic. There is no hard and fast rule on the number of replicates; however, 1,000 replicates should suffice.
- Determining for each replicate the storage size using an appropriate technique, e.g., the mass curve, SPA, or a BA. The 1,000 size estimates then constitute the “population” of sizes.
- Analyzing the “population” of sizes to determine summary statistics such as the mean, standard deviation, Cv, median, skew, empirical distribution function, various quantiles, etc., of reservoir size.

The standard deviation (or better still the Cv) estimated in the fifth step above is a measure of the standard error (or uncertainty) in the capacity estimate. This uncertainty will increase as the record length increases, as illustrated in Figure 4.

The above description assumes that seasonality in inflow and demand is insignificant. Where there is a strong inflow seasonality, then seasonal flows must be generated stochastically, either directly using a seasonal stochastic model or indirectly by disaggregating from generated annual flows (see McMahon and Adeloje, 2005). Another issue of note in using the Monte Carlo approach relates to parameter uncertainty. The parameters for driving the stochastic model are subject to uncertainty by virtue of the fact that they are obtained from a limited historic data record. Consideration of parameter uncertainty introduces an additional layer of complexity, but this may be unavoidable in certain situations, e.g., in highly variable rivers (see Montaseri and Adeloje, 1999). McMahon and Adeloje (2005) describe the procedures for incorporating parameter uncertainty in AR-1 flow generation models.

2. Optimization

Constrained optimization solution of reservoir sizing problems is also widely practiced as reviewed by Yeh (1985). An optimization formulation requires an objective function and a set of constraints. Depending on the particular problem, solution is then sought using linear programming (LP), dynamic programming (DP), non-linear programming (NLP), or some of the emerging techniques based on evolutionary programming of which genetic algorithms (GA) are the most popular.

Of the available solution algorithms, the LP is the most commonly used for reservoir sizing. As the name implies,

Hydrological Sizing of Water Supply Reservoirs, Figure 4 Effect of runoff record length on the variability of reservoir size estimates for (a) a river in Yorkshire, England, and (b) a river in Urmia Region, northwest Iran. MAF is the mean annual flow. (Adapted from Montaseri and Adeloye, 1999.)

both the objective function and the constraint equations must be linear in the decision variables for linear programming; otherwise appropriate linearization of these functions must be carried out to apply LP.

For the typical sizing of a single reservoir, the objective function is the minimization of the capacity, i.e.,:

$$\text{Min } (K_a) \quad (17)$$

The associated constraint equations are:

Reservoir mass balance

$$S_{t+1} = S_t + Q_t - D_t \quad (18a)$$

Size constraint

$$S_{t+1} \leq K_a \quad (18b)$$

Non-negativity constraint

$$0 \leq S_{t+1} \quad (18c)$$

Other constraints might include a limit on the size of K_a due to environmental considerations and a limit on S_{t+1} in certain seasons to accommodate, e.g., flood water. McMahon and Adeloye (2005) contain examples of several LP problem formulations for the planning of reservoir sizing. An attractive and unique feature of optimization is that the objective function can contain economic and non-economic factors, implying that costs and benefits (both financial and environmental) of the reservoir development can be considered in the size planning analysis. For single reservoir problems, consideration of actual costs and benefits in the objective function is not crucial because a minimization of the reservoir size is the same as a minimization of the cost for a single variable problem. This may not be the case for complex, multiple reservoir configurations.

3. Probability matrix method

The transition probability matrix (TPM) methods model the reservoir states (or storage) directly as a stochastic process. This is the main difference between these approaches and those described earlier in which the focus was the inflow.

The transition probability matrix method emanated from the seminal work on the theory of storage by Moran (1959), and although refinements to the method have since occurred (see McMahon and Adeloye, 2005; Zsuffa and Galai, 1987), the method is not as popular as the sequential methods based on streamflow analysis. Indeed, concerted efforts in developing the TPM have been restricted to parts of Eastern Europe, notably in the countries of the former Soviet Union. Nonetheless, the TPM methods do offer some added benefits in that the estimated size is independent of any assumptions made about the initial starting conditions and secondly, the performance (e.g., failure probability) can be computed either at steady state or as a time-dependent function (McMahon and Adeloye, 2005).

Conclusion

Hydrological sizing of water supply reservoirs is important to ensure that the reservoir will meet the demand with an acceptable level of performance. The methods described in this short article are by no means the only ones available. However, they have been selected because they are among those commonly applied, and some of them, by requiring limited data input, are readily applicable at ungauged and sparsely gauged reservoir development sites. This is particularly significant in developing country economies of the world where the problem of lack of data is the most serious and where paradoxically the need for planning and design of new reservoirs is still prevalent.

HYDROPOWER

Hans Bergh

Department of Hydraulic Engineering, Royal Institute of Technology, Stockholm, Sweden

Description

In a hydroelectric power plant, the potential energy represented by the difference in elevation between a headwater surface above and the tailwater below the power plant is transferred to electricity by letting the water pass through a turbine which in turn drives an electric generator. This energy originates from the solar radiation which is the driving force of transport of moisture evaporated from the oceans and inland lakes, and transport of moisture which condensate in the atmosphere forming precipitation on high altitudes.

The main components in a hydroelectric power plant are (Figure 1):

The dam, with the purpose of blocking the watercourse so that the water intended for the hydropower production does not pass through the power plant via the natural river channel. It is intended to raise the water level in the watercourse, thus creating an increased head and a reservoir.

The headrace conduit, conveys the water from the reservoir to the turbine. The conduit can be a channel, flume, penstock, tunnel, or combinations of these. The length of the headrace can vary from a few meters to several kilometers.

The intake, located in the upstream end of the headrace, is the transition between the reservoir and the headrace. In the intake is a trash rack preventing debris, ice, fish,

Hydropower, Figure 1 General layout of a hydropower plant.

etc., from entering the headrace and a gate as well for closing of the intake.

The *power station* is where the energy of the water is transferred to mechanical energy in the turbine, and from mechanical energy to electrical energy in the generator.

The *tailrace* conveys the water from the power station back to the natural watercourse. It can be a channel or tunnel or a combination and have lengths as that of the headrace, from meters to several kilometers.

Hydroelectric power plants can be classified in several ways, for example, in terms of installed capacity (micro, mini, or ordinary hydro), in terms of head (low, medium or high head) or in terms of operative mode (storage, run of river or pumped-storage). In the storage plant type, water from the wet season is stored in a reservoir and used for power production during the dry period. In the run of river-type plant, the storage capacity is limited, and the water in the stream is used only as it comes. In the pumped-storage plant, water is pumped from a tailwater reservoir to a headwater reservoir on a higher elevation during periods with a small energy demand (e.g., at night when the cost of energy is small). During periods with high energy demand (e.g., daytime when the value of the energy is high) the pump is reversed to act as a turbine as the headwater reservoir is emptied.

The difference in elevation between the water level in the upstream reservoir and the water level at the point in the water course where the water is conveyed back after having passed the turbine is called the *gross head*. The head utilized for energy production after deducting the energy losses intakes, head and tailrace conduits, etc., is called the *net head*.

The power P (W) produced in a hydroelectric power plant $P = \eta \rho g Q H$, where H = net head (m),

Q = flow rate (m^3/s), g = acceleration of gravity (m/s^2), ρ = density of water (kg/m^3), and η = efficiency factor, considering energy losses in the turbine, generator, and transformer.

Major advantages of hydropower are that it is renewable, produces no carbon dioxide except for a limited amount during construction, and is cost effective.

Some disadvantages of hydropower reservoirs are loss of land, damage on the ecosystem, and sometimes relocation of people living in the planned reservoir area. Reservoirs can produce methane if forests have not been cut before filling of the reservoir, particularly in tropical regions. If the river carries sediment that is deposited in the reservoir, the water passing the power plant contains very little sediment, which can lead to scouring of the beds and banks of the river downstream of the dam.

ICE COVERED LAKES

Lars Bengtsson
Department of Water Resources Engineering,
Lund University, Lund, Sweden

Ice formation

Lakes at high latitudes or high altitudes are ice covered part of the year; typically from November to April and in the very north sometimes from October to early June. Arctic lakes may be ice covered throughout the year. When there is a regular ice cover for several months, the ice thickness reaches more than $\frac{1}{2}$ meter. At mid latitudes occasional ice cover may appear for short periods several times during a winter. Where there is a stable ice cover, ice roads are prepared. Fishing is done also at commercial scale. Ice covered lakes are used for recreation.

Ice on a small lake is formed rather quickly after the surface water is cooled down to the freezing point – most often after a cold night with no wind. It takes much longer time for a large lake to freeze-over than a small lake, since relatively warm water is brought to the surface during the more intense mixing in a large lake. Ice on lakes grows in a static way; there is no horizontal transfer of ice but the ice grows in the vertical. Ice is produced as black ice, when heat is lost to the cold atmosphere from the water underneath the ice, or as snow ice, when the ice is suppressed under the water surface by heavy snow and water freezes in the slush layer in the snow on top of the ice. Once ice is formed it grows rather quickly in the first weeks until the ice cover and snow on the ice insulate the water from the atmosphere; the rate of ice growth is slowed down. The heat lost from the water to the atmosphere must be taken from the latent heat released when ice is formed, since the water just below the ice is at the freezing point.

Ice formed from the underside of the ice sheet has crystals with columnar structure; it is possible to see through the ice. Such ice is called black ice. Ice can also be formed in a slush layer between the snow and the top of the ice. When the weight of the snow is more than the lifting force from the ice, the ice cover is forced under the water surface and water enters into the snow which becomes saturated with water. When this slush layer freezes, snow ice or white ice is formed. The crystals in this kind of ice are randomly distributed. This ice is not transparent but looks somewhat like milk. An example of ice growth is shown in [Figure 1](#) from a bay in the Luleå archipelago (almost fresh water).

The ice on a lake has ecological consequences. Since there is no exchange with the atmosphere, the oxygen content of the water decreases and the bottom layers may be completely depleted of oxygen. Man's impact on lake ice is mainly from release of oxygen consumption substances, which increases the rate at which the lake water is depleted in oxygen. All releases from industries and waste water treatment plants and also the increased winter flows in regulated rivers have local effects on the ice cover.

Thermal regime

The thermal regime of ice covered lakes considers the heat fluxes to and from a water body without direct contact with the atmosphere, the temperature distribution over the depth, and how it changes during the ice covered period. In the autumn after the surface water is cooled to 4°C and the water has turned over, the warmest water in a lake is that of the highest density. The surface water is colder than the bottom water. If there is a very cold period shortly after the turnover, a wind-sheltered lake may freeze-over when the water not far from the surface and downward is still 4°C. In another year the turnover may be followed by an extended windy period with air

Ice Covered Lakes, Figure 1 Observed ice growth in the inner archipelago in Luleå, Sweden. Snow depth on the ice is shown and separately the snow ice growth. The dotted line is the computed ice thickness using a degree-day approach. Measurements by the author.

temperatures fluctuating around 0°C resulting in a reduction of the lake water temperature down to considerable depths. The initial temperature profile after freeze-over is quite different for the two situations.

Once a lake has a stable ice cover the lake water is more or less insulated from the atmosphere. The heat lost to the cold atmosphere is taken from the latent heat released from the ice growth. There is a small sensible heat flux from the water to the underside of the ice. The major heat flux in an ice covered lake is that from the sediments to the lake water. Heat stored in the sediment from summer to winter is released. The lake water temperature increases in the course of the winter, see Figure 2 from Lake Velen in Sweden. Lakes in cold long winter climate tend to be warmer than lakes in milder climate with less stable winters. In the milder climate the lakes freeze-over later, when they have cooled down throughout the vertical, and also in the milder climate the lake ice may break up several times during winter allowing wind mixing and heat losses directly to the atmosphere. The bottom temperature is often 4°C already at the time of freeze-up; if not, because of the contribution of heat from the sediments this temperature is approached in the course of the winter. The bottom temperature may even be slightly higher than 4°C, due to diffusion of solutes from muddy sediments.

The change of the heat content, dH/dt in an ice covered lake is

$$\frac{dH}{dt} = \rho c_p \int A(z) \frac{\delta T}{\delta t} dz$$

$$= (H_{sed} + R_{netsol} - H_{ice})A_{surface} + H_Q$$

where T is temperature, z vertical distance, t time, c_p specific heat capacity, and ρ is density of water and $A(z)$ is area at depth z .

The sediment heat flux per unit area, H_{sed} , is the most important heat flux. The sediment heat flux at shallow

Ice Covered Lakes, Figure 2 Temperature in ice covered Lake Velen, mean depth 6.5 m, max depth 17 m, lake area 2.8 km².

water may be in the range 4–10 W/m² in early winter and reduce to 1–3 W/m² in late winter. At the deep part of a lake it is smaller, 2–3 W/m² in early winter and less than 1 W/m² prior to breakup.

The heat advection, H_Q , with the through-flow is very small in most lakes, since the river through-flow per unit lake area is small and the temperature of the inflowing river water is very close to 0°C. In narrow fjord lakes the flow per unit area may be substantial. However, in such lakes a thermocline develops so that the river runs through the lake within a top layer of 0°C temperature. The heat loss, apart from that of the heat loss with outflowing water,

is the sensible heat flux from the water to the underside of the ice, H_{ice} . A pronounced temperature gradient develops close to the underside of the ice. A viscous sublayer develops. The heat flux is $1\text{--}2\text{ W/m}^2$ in most lakes but can be rather much higher in late spring, when solar radiation penetrates the ice. The intensity of the solar radiation, which penetrates the ice is denoted $R_{net\text{sol}}$.

In spring when the snow on the ice melts, solar radiation can penetrate the ice and heat the water below. Although only a small fraction of the solar radiation reaches the lake water, the flux is higher than the other fluxes in an ice covered lake. Depending on the ice character and the ice thickness and time of year the solar radiation penetrating the ice is $10\text{--}40\text{ W/m}^2$, partly compensated for by increased heat transfer from the water to the ice.

Circulation and mixing in ice covered lakes

Knowledge about circulation processes in lakes is essential when planning for the use of a lake for water supply or receiving waters. The conditions controlling the dynamics of ice covered lakes are different from those of an ice-free lake. The ice cover prevents direct generation of wind mixing. The water movements are much determined by thermal processes and by the vertical movement of the ice cover. There are also oscillations caused by the setup of the ice surface by the wind. River inflows induce some circulation close to the inlet. While the currents in ice-free lakes are typically 2% of the wind speed, that is, 20 cm/s when the wind is 10 m/s, the currents in an ice covered lake are very much lower. The oscillation movements may be 1 cm/s back and forth. The currents caused by thermal processes are of the order mm/s or even less. Still these movements result in vertical mixing and changed temperature conditions in the course of the winter.

The thermal conditions and the heat fluxes are responsible for convection and mixing of different character. Heat accumulated in the sediments during summer is released to the water in ice covered lakes. When the water gains heat from the sediment it becomes warmer and denser and the water slides downward generating a large convection cell. A different form of more local convection is generated for a short period in the late spring, when solar radiation can penetrate snow-free ice. Density instabilities arise and a top mixing layer develops.

Water which gains heat from the sediment near the shores moves slowly along the bottom toward the deeper parts of the lake, generating large convective circulation cells as shown in Figure 3. The velocities involved seem to be well below 1 mm/s. It is possible to determine a vertical mixing coefficient from the change over time of the vertical temperature profile. The thermal vertical diffusivity is well below $0.1\text{ cm}^2/\text{s}$. The bottom water is mixed due to the convection induced by the heat flow from the sediments. However, once the water has reached the temperature of maximum density, 4°C , the water does not take part in the mixing process; the convection takes

place above this 4°C water. The bottom water in subbasins of a lake may be isolated from the water in the main basin and remain stagnant for many months.

When the solar radiation is able to penetrate through the ice, the water below the ice gains heat and becomes denser than the water further down. Convective mixing is initiated as the warm water sinks. A mixed layer may develop down to considerable depths depending on how far the shortwave radiation reaches, thus depending on the extinction coefficient of the lake water and how much solar radiation penetrates the ice. The mixed layer deepens rather fast, maybe 0.5 m/day . An example of deepening of the mixed layer is shown in Figure 4.

When a wind acts on the ice of a lake, the ice cover is tilted and oscillates. The water particles underneath are forced to move back and forth over short distances, in the order of meters. The maximum velocities in lakes $1\text{--}10\text{ km}^2$ seems to be $1\text{--}3\text{ cm/s}$. The net movement is close to nil, but mixing occurs and particles are dispersed. Some kind of oscillatory currents are always present in ice covered lakes and they significantly contribute to the

Ice Covered Lakes, Figure 3 The principle of large-scale convective circulation generated by heat flux from sediment to water.

Ice Covered Lakes, Figure 4 Convective mixing in Lake Vendyurskoe due to penetration of solar radiation through the ice. Ice thickness 0.5 m.

horizontal mixing. Dye experiments in Swedish lakes, where the oscillation period is about 20 min, have shown that the horizontal dispersion coefficient is in the range 10–200 cm²/s.

A river which runs through a lake generates currents, but after initial mixing near the inlet the river water can be traced only if the river is large. In ice covered lakes, thinner ice on the right-hand side indicating upwelling of warm bottom water with secondary currents induced as an effect of the Earth's rotation has been observed, but most studies show that the current is rather uniformly directed in the upper part of a cross section. When the river flow is large and the lake elongated like a fjord lake, a cold top layer, where the flow takes place, develops over a pronounced thermocline separating the cold layer from a warmer bottom layer.

Summary

Although a lake is ice covered there is mixing and slow currents below the ice. Currents are generated by river through-flow, by oscillation of the ice cover, and by heat released from the sediments. The net currents are of the order mm/s, but still important for the vertical mixing and the development of the temperature profile. The knowledge of the thermal conditions in lakes is essential when planning for water intakes, so that desirable water is provided, or planning for discharge of effluents, so that recirculation is avoided. Withdrawal and release of water may affect the thermal conditions and generate mixing. Regulation of rivers causing winter flows to be higher than the natural ones may influence the temperature in an ice covered lake.

ICE FORMATION ON LAKES AND ICE GROWTH

Lars Bengtsson
 Department of Water Resources Engineering,
 Lund University, Lund, Sweden

Description

Ice forms when the surface water temperature drops to the freezing point. In calm water, the ice grows fast from the shore outward. A small lake becomes ice covered overnight. As long as the ice is thin, it may be broken by strong winds. Lake ice grows in a *static way*, which means that the ice production is only within a vertical and a consequence of vertical heat losses to the atmosphere. The ice is not progressing in any horizontal direction due to currents or floating ice.

When there is no or little snow on the ice, the ice grows from the bottom of the ice cover. *Black ice* or columnar ice is produced. The ice is transparent with the molecules oriented vertically. Heat lost through conduction through

the ice cover, and the snow above is taken from the heat released when ice is produced. The lower the air temperature is, and the thinner the ice is, the faster the ice growth is.

After heavy snowfall, the snow on the ice may become too heavy to be supported by the ice cover without the ice cover being suppressed under the water surface. Water enters into the snow. A slush layer of saturated compressed snow is formed on top of the ice and below the dry snow. Now the heat loss to the cold atmosphere is compensated, for by ice formation within this slush layer, *snow ice* or white ice is formed. This ice has a milky character. The molecules are randomly distributed. The typical winter condition with thick black ice as the lowest layer, snow ice above, and snow on top of the ice is illustrated in the [Figure 1](#).

Since the heat is lost to the atmosphere through conduction, it is fairly easy to estimate the ice growth. The heat loss is

$$H_{\text{loss}} = \frac{-T_a}{h_{\text{ice}}/\lambda_{\text{ice}} + h_{\text{snow}}/\lambda_{\text{snow}} + m}$$

where T_a is the air temperature, h with different index denotes thickness, λ denotes heat conduction coefficient, and m is surface resistance. The surface resistance is of importance only just after lake freeze-over unless the snow surface temperature deviates much from the air temperature.

The heat generated through ice production is

$$H_{\text{generated}} = \phi_i F \frac{dh_i}{dt}$$

where F is latent heat of fusion, ϕ_i is density of ice, and t is time.

Ice Formation on Lakes and Ice Growth, Figure 1 Typical lake ice conditions.

When there is no snow on the ice, putting the generated heat equal to the heat loss, the ice thickness is (initial ice thickness = 0) described with a degree-day approach as

$$h_i = C S^{1/2}$$

where S is number of negative degree-days, i.e., accumulated daily negative temperature, and C is a degree-day coefficient which is found when putting the generated heat equal to the heat loss,

$$C = \left(\frac{2\lambda}{\phi_i F} \right)^{1/2}$$

with λ as λ_i when the ice is free from snow. If not, an effective value must be used, which can be determined from the heat loss equation above. The degree-day coefficient is $3.5 \text{ cm}/(^{\circ}\text{C-d})^{1/2}$ for snow-free ice. For the more common situation with snow on the ice, C is about $2 \text{ cm}/(^{\circ}\text{C-d})^{1/2}$.

The snow depth on lake ice is restricted by the capacity of the ice to support the snow load without the ice surface being submerged under the water surface. From Archimedes principle, it is easily found that the maximum snow depth can not ice over a period longer than a few days is

$$h_{\text{snow}} = \frac{\phi_{\text{water}} - \phi_{\text{ice}}}{\phi_{\text{snow}}} h_{\text{ice}}$$

For typical density of snow on ice, relative density 0.3, the snow depth can not exceed 0.3 of the ice thickness.

From the degree-day equation, it is clear that lake ice grows slower and slower in the course of the winter. In an environment where it snow regularly and the air temperature is almost constant -5°C , the ice grows to 12 cm in a week, to 17 cm after 2 weeks, 24 cm after a month, 35 cm after 2 months, and 42 cm after 3 months.

ICELANDIC LAKES, PHYSICAL CHARACTERISTICS

Hrund Ó. Andradóttir
Reykjavík, Iceland

Introduction

Iceland is a 103,000-km² volcanic island situated on the Mid-Atlantic Ridge, just south of the Arctic Circle. Because of its geographical location, the country boasts both of glaciers and volcanos, earning itself the nickname “country of fire and ice.”

Icelandic surface waters are classified based on their source. Sixty percent of the annual runoff is direct, the remainder is evenly divided between springwater and glacial meltwater (Bjornsson et al., 2008). Lakes cover 2.7% of the country’s surface area, ninety percent of which are smaller than 1 km² (Adalsteinsson, 1987). Lake Thorisvatn is the largest lake (88 km²). Other largest and best known Icelandic lakes summarized in Table 1. Lake Thingvallavatn and Lagarfljot, both deep lakes, with a residence time of almost 1 year, and shallow. Lake Myvatn, with a residence time of approximately 1 month.

Icelandic lakes have provided many important socio-economic functions in the past and present. Considering the four largest lakes, Lake Thorisvatn serves as a storage reservoir for hydroelectricity production. Lake Thingvallavatn and Lake Myvatn (shown on Figure 1) are major touristic attractions, renowned for their wildlife, landscapes, and recreational fishing. The ice-covered Lake Lagarfljot was an important transportation route in the wintertime (Hallgrímsson, 2005).

Building upon the extensive research conducted in Lakes Thingvallavatn, Lagarfljot, and Myvatn, this entry discusses some of the physical features distinguishing Icelandic lakes from others. First, the meteorology and annual thermal cycles are introduced. Then, the fate of groundwater and glacial inflows is discussed. Water circulation in shallow and deep lakes is subsequently contrasted. Lastly, observations and predictions of physical limnological changes due to global warming and human activities are presented.

Meteorology

The Icelandic climate is influenced by the warm waters of the North Atlantic Current. The annual temperature cycle

is moderate, considering the northern location, with monthly mean air temperatures in lowlands (<400 m a.s.l.) ranging from −2°C in winter to 9°C in summer. The maximum average daily temperature in summer time is 16°C (Bjornsson et al., 2007). The climate is also characterized by strong winds, with monthly mean wind speeds ranging between 2 and 7 m/s, and frequent precipitation (Andradóttir, 2008; Bjornsson and Jonsson, 2003).

Thermal cycle

Icelandic surface waters have been found to follow a similar seasonal thermal cycle as air, reaching temperatures as high as 10–14°C in summer (Rist, 1990). Vertical temperature profiling suggests that the majority of Icelandic lakes do not undergo a persistent summer stratification (Malmquist et al., 2010). This is particularly true for shallow systems (<30 m) where wind mixing prevents the formation of a seasonal thermocline. The 100 m deep Lake Thingvallavatn and Lake Lagarfljot, are known to stratify in summer. Their summer stratification is both short lived, lasting solely 2–3 months, and weak with a gradient of 1–3°C across the thermocline (Adalsteinsson et al., 1992; Andradóttir, 2008; Helgason and Axelsson, 2009). The thermal stratification starts developing in June and is fully established by early July. The stratification is destroyed during fall turnover in September, after which the lake water cools uniformly down to 0–2°C. Once this temperature has been reached, the lakes may begin to freeze.

Historical research suggests that the duration of the ice cover varies significantly between lakes of different depths. Table 2 demonstrates, for example, that Lake Thingvallavatn, with maximum depth exceeding 100 m and long residence time (see Table 1), was, on average, ice-covered for 3 months. In contrast, shallow Lake Myvatn began freezing in fall and stayed frozen for approximately 6 months. This difference can be explained by the larger thermal inertia of the deeper Lake Thingvallavatn, which results in slower response to convective cooling. Limited vertical temperature measurements have been performed during periods of ice cover. The few winter profiles from Lakes Thingvallavatn and Myvatn suggest that the water column was inversely stratified, with mean temperature around 1°C. Hence, deep lakes, such as Lake Thingvallavatn, are classified as dimictic, and shallow lakes, as polymictic.

Icelandic Lakes, Physical Characteristics, Table 1 Physical dimensions of largest Icelandic natural lakes

Lake	Lat.	Z (m a.s.l.)	A (km ²)	Mean depth (m)	Max. depth (m)	Residence time (days)	Formation
Thingvallavatn ^a	64°10'	100	82	34	114	330	Subsidence, hyaloclastite and lava dam
Lagarfljot ^b	65°10'	20	53	51	112	270	Glacier-eroded valley lake

Groundwater and glacial inflows

Inflow dynamics

Inflow dynamics – that is, whether inflows enter as surface intrusions or submerged underflows – is determined by the density of the inflows relative to the lake. Icelandic lakes are unique in that many of them are fed by groundwater and/or glacial rivers. The different physical and chemical composition of these sources influences their fate and lake water quality.

First, consider Lake Thingvallavatn and Lake Myvatn, both of which are situated on the neovolcanic rift zone which crosses Iceland from SW to NE. The lakes' catchment areas are mostly postglacial lavas transected by numerous faults and fissures. Precipitation and glacial melt percolate directly into the highly permeable volcanic strata. The mineral-rich water, thus, enters the lakes through warm (>25°C), moderately warm (10°C), and/or cold (3–5°C) subsurface springs (Olafsson, 1979; Adalsteinsson et al., 1992). The origins, characteristics, and quantities of the groundwater inflows to the lakes have been assessed through physical and chemical observations, tracer studies, and groundwater modeling (Kristmannsdottir and Armannsson, 2004; Olafsson, 1992; Vatnaskil Consulting Engineers 2000). The inflow dynamics is found to be primarily governed by the

temperature anomaly between the spring and lake water (Andradottir et al., 2009). Unlike surface water, which varies from 0°C to 2°C temperature in winter and from 10°C to 14°C in summer, as discussed earlier, groundwater temperature remains constant over the course of the year. Consequently, the warm spring water with temperatures exceeding 15°C enters the lakes as a surface intrusion independent of season. Conversely, the cold spring water with temperature close to that of maximum density (3–5°C) enters the lakes as a negatively buoyant underflow most of year. Wind mixing in shallow littoral regions can significantly enhance the dilution of negatively buoyant spring water with lake water, which may reduce the intrusion depth in the lake (Forrest et al., *in press*).

Next, consider Lake Lagarfljot in Eastern Iceland. The strata in this region are both older and less porous than in the neovolcanic zone discussed earlier. Hence, lake inflows are predominantly surface rivers, as opposed to underground springs. The major inflow to Lake Lagarfljot was historically glacial river Jokulsa i Fljotsdal. After the Karahnjukar hydropower plant became operational in 2007, the lake also receives dammed glacial water from Jokulsa a Dal. In contrast to the steady springs, glacial rivers undergo drastic seasonal variations in flow rate and chemical composition. Figure 2a shows that historical

Icelandic Lakes, Physical Characteristics, Figure 2 Comparison of monthly physical characteristics of glacial river Jokulsa i Fljotsdal and Lake Lagarfljot prior to damming. (a) Suspended sediment concentration (1963–1997), (b) water temperature (2001–2007), and (c) calculated density difference (Andradottir, 2008).

suspended sediment concentrations in Jokulsa i Fljotsdal can reach 400 mg/l during summer high flows (70 m³/s). This is approximately tenfold the 20–50 mg/l suspended sediment concentration within Lake Lagarfljot. In winter, the flow rates and suspended sediment concentrations drop to 7 m³/s and 40 mg/l, respectively (Jonsson et al., 1999; Hardardottir and Thorlaksdottir, 2004). The fine glacial sediment inputs substantially reduce the light penetration in the lake (Adalsteinsson, 1976) and give the lake a distinguished milky gray color (see Figure 3). Originating from a melting ice cap, glacial rivers are often colder than direct runoff and spring fed rivers in summer. Figure 2b shows that glacial river Jokulsa i Fljotsdal historically peaks at 6°C, while Lake Lagarfljot surface waters reach 10°C. The fate of the glacial river inflow is, hence, both determined by the suspended sediment concentration and temperature relative to that of the lake. The combined effect is portrayed on Figure 2c, which shows a strong seasonal cycle, with negatively buoyant sediment-rich underflows in the summer and surface intrusions in the winter.

Ecological implications

Inflows are a major source of oxygen, nutrients and other land borne chemicals to aquatic systems. Their initial fate, determined by the inflow dynamics, can influence lake water quality and ecological functions. The cold submerging groundwater inflows to Lake Thingvallavatn contribute to nutrient deficiency in surface waters in summer. This leads to an abrupt 70% drop in primary production in the water column in a matter of days after the thermocline is developed (Jonasson et al., 1992). Primary production is enhanced again during fall turnover when nutrients

that have been accumulating in the bottom waters are mixed throughout the water column.

Less dense surface inflows, due to either geothermal spring or glacial water, are likely to short-circuit at the lake surface in the absence of wind mixing, limiting renewal of bottom water. As a result, oxygen depletion is known to occur in late winters, especially in shallow Icelandic lakes, such as Lake Myvatn (Einarsson et al., 2004).

Inflows can also affect spatial variability. For Lake Myvatn, the heterogeneity of groundwater temperature and chemical composition contribute to a range of ecological diversity (Einarsson et al., 2004). Figure 4, for example, shows the difference in macrophyte communities in the north basin of Lake Myvatn, which receives warm spring water; east basin, which receives cold spring water; and south basin, which is disconnected from the east basin through a series of islands.

Water circulation

Lake circulation is governed by the drivers that generate motions and the morphometry which constrains them. First, consider shallow Lake Myvatn. The lake is physically divided into three main basins, as discussed earlier (see Figure 4). During ice cover and/or low winds, water exchanges between lake basins are governed by horizontal density gradients primarily imposed by cold and warm artesian springs and modified by diurnal differential heating and cooling (Palmarsson et al., 2010). The general flow in the south basin is from the inlets in the east toward the outlet in west (Olafsson, 1979). Resuspension of sediments is low, and the nutrient concentrations build up in the sediment pore waters (Einarsson et al., 2004). During ice-free conditions, two wind-induced counterrotating

Icelandic Lakes, Physical Characteristics, Figure 3 Distinctive gray color of Lake Lagarfljot in Eastern Iceland, arising from sediment-rich glacial inflows. (Photo: Hrund Andradottir.)

Icelandic Lakes, Physical Characteristics, Figure 4 Spatial variability of macrophytes in Lake Myvatn in relation to warm and cold groundwater springs. (Modified from Einarsson et al., 2004.)

gyres prevail in the south and east basins. The water column is well mixed, validated with observations and depth-averaged hydrodynamical modeling (Kjara et al., 2004; Johannesson, 1991). Wind-driven sediment resuspension and mixing play an important role in releasing nutrients back into the water column, with peaks occurring in spring (Einarsson et al., 2004).

The wind is also the major driving mechanism in weakly stratified deep Icelandic lakes. Results from thermistor chain monitoring in narrow Lake Lagarfljot in summer of 2008, displayed on Figure 5, clearly demonstrate regular oscillations which correspond to basin-scale internal seiches moving along the length of the lake with periods on the order of 1–10 days (Andradottir, 2010).

These slow internal seiches are the key driver for motion, responsible for 5 cm/s near bed velocities along the main lake axis and 3–8 m vertical displacements. The spreading of the temperature time series around Julian day 200 in Figure 5 indicates the presence of vertical modes.

Changing climate and land use

Air temperature increased on average by 0.7°C in the last century in Iceland. Greatest trends were observed in winter temperatures, which increased by 1.2°C over this period (Bjornsson et al., 2008). As water temperature is closely correlated with air temperatures, this warming can have significant winter limnological implications. Ice cover is already observed to be more short lived and

Icelandic Lakes, Physical Characteristics, Figure 5 Filtered water temperatures at different depths in Lake Lagarfljot, July to October 2008. Colors' caption: 9 m (blue), 13 m (green), 19 m (red), 25 m (cyan), 29 m (violet) to 37 m (green) depth (Andradottir, 2010).

intermittent in space and time. Ice cover at Lake Thingvallavatn has been lasting, on average, 5 weeks since 2001, and two winters were completely ice-free (Sveinbjornsson, 2009). This is a drastic change from the 3-month ice cover period historically observed from January to April (Table 2). With shorter duration of ice cover, the likelihood of winter stratification and oxygen depletions is diminished.

While the trend in summer air temperature was insignificant over the last century, a substantial increase has been observed in the past decade. Recent study in shallow Lake Ellidavatn suggests that water temperatures have been increasing in the past 20 years. At the same time, a decline in Arctic charr was observed (Malmquist et al., 2009). New thermistor chain data from Lake Thingvallavatn (Ingimarsson et al., 2011) suggest that deeper lakes may be stratifying for a longer period of time with a stronger gradient (3–4°C) across the thermocline.

With rising air temperatures, Icelandic glaciers have been retreating at a fast rate (Bjornsson et al., 2008). This leads to an increased summer runoff in watersheds dominated by glacial melt, which, in turn, has implications on lakes' residence time, water circulation, and quality. In addition, excessive glacial retreat may alter the flow rate, temperature, and chemical characteristics of groundwater inflows to lakes, such as Lake Thingvallavatn (Palmarsson et al., 2010). Global climate change is also predicted to alter runoff patterns in nonglacial watersheds, with less precipitation falling as snow and more snowmelt in winters (Bjornsson et al., 2008).

Lastly, the damming of glacial rivers alters their temperature, chemical composition, and flow rates (Malmquist, 1998). With the damming of Jokulsa i Dal, glacial water stored in Halslon reservoir is now channelled to Lake Lagarfljot. Results from the first 2 years of this operation suggest that summer suspended sediment concentrations inside the lake have doubled to 100 mg/l

and light transmissivity has halved to 50–60 cm (Adalsteinsson, 2010). This increased suspended sediment concentration within the lake may influence the fate of the inflowing water, reducing the depth and possibly the duration of underflows.

Summary

The physics of subarctic Icelandic lakes differ from those of temperate lakes in several ways. First, the thermal regime is very moderate, and at best, lakes develop a weak (0.1°C/m) and short-lived summer stratification, lasting from June to September. Secondly, many lakes are primarily fed by spring or glacial water, with distinctive physical and chemical properties. Warm groundwater in geothermally active regions enters lakes as surface intrusions, which may contribute to short-circuiting and oxygen depletion, especially during prolonged periods of ice cover. In contrast, cold mineral-rich spring water and sediment-rich glacial river water submerge as they enter lakes, leading to bottom renewal but also nutrient deficiency in the epilimnion. Third, warm and cold artesian springs can coexist in the same lake, driving lateral exchange flows and spatial variability in ecological functions. Fourth, the climate is characterized by strong winds. Shallow systems are often well mixed with depth, where wind resuspension and mixing play an important role in releasing nutrients from the sediments into the water column after prolonged periods of ice cover. The hydraulic regime in deep lakes is characterized by slow wind-driven internal seiches with periods on the order of days. Lastly, global warming is affecting air temperatures, glacial melt, and runoff regimes in Iceland. This, in turn, can have physical, chemical, and biological implications on lake inflows and lake water quality. Shorter periods of lake ice cover are observed, thereby reducing the likelihood of late winter oxygen depletion. There are indications of increasing water temperatures in shallow systems and increased thermal stratification in deeper systems.

INDIAN LAKES

V. K. Dwivedi
 National Institute of Technology, Durgapur, India

Introduction

Being valuable natural resource, lakes have always been of great importance to mankind. From ancient times these have been providing water for domestic use. Since long, lake water is being used for industrial purposes as well as for irrigation. Lake is also one of the means of transport and has always attracted the attention of human beings for

recreation. Some of saline lakes are useful sources of some important minerals as well. In short, a lake is a sort of catalyst in the development of the city, region, and the country as a whole. But, unfortunately, the popularity of lakes often leads to its deterioration. The increased input of industrial and domestic waste and sediments and the human activities not only hamper the capacity of the lake but also cause an increase in the productivity of the lake resulting in the biological and chemical changes leading to hazards like death of fish, obnoxious odor, and unsightly conditions.

A lake is easy to visualize because of its definitive boundary like other types of storage. Lakes are natural reservoirs in which water is temporarily stored during its passage to sea. These receive water as precipitation on their surface, from surface influence and from ground water entering as springs. Lake loses water in the form of evaporation, outflowing streams, contribution to groundwater, etc. Lakes disappear through a process of natural eutrophication involving the nutrients containing sediments. The process of cultural or man-made eutrophication is faster than the natural eutrophication. A distinction between lake and reservoir is that the latter is either a man-made lake or a natural lake augmented with some type of regulation mechanism.

Hydrologic characteristics of lakes vary considerably because of difference in depth, surface area, climate, inflows, and outflows. Lakes may have common features but often exhibit different performance characteristics. Hence, each lake requires its own hydrologic models and these models need to be characterized by different degrees of variance from a generalized conceptual model.

Lakes also exist in all sizes and it is obvious that a small pond of 0.01 km^2 is totally different in most ways than, lake of 50 km^2 . Climate, geology, and anthropogenic influences are other factors that make each lake unique.

Lake has its hydrologic response. It has cause and effect relationship with the adjoining catchment. Because of storage of large mass of water, it moderates flood and climatic factors in the region. Also the deforestation, conversion of grassland to cropland, intensification of agricultural production, land amelioration, etc., in the nearby catchment area affect the microclimate and reduce evapotranspiration thereby increasing runoff and rate of erosion and siltation. Accelerated nutrient cycles and faster transport of soil particles increase rate of sediment deposition and lead to enrichment of stored water. Therefore, various physical, chemical, and biological inputs manifested through the hydrology of the catchment and lake affect the quality and quantity of the stored water.

Lakes of India

Water in rivers and lakes amount to be about 1% of the water budget but its importance to life and human geography is enormous. It is estimated that the world's lakes contain about four times freshwater than its rivers. Lakes are used extensively by people in many countries as the natural centers of civilization. Following the world trend lakes

have been the first priority of available natural resources for development of civilization. In Western India, even during the Maurya period (320 BC) a major reservoir called "Sudarshana lake" was made at the foot of Mount Girnar (Wunderlich et al., 1987). Also the lakes in India have been extensively utilized resulting in overexploitation.

In India, natural and/or man-made changes in storage of lakes, both in quality and quantity of water, have altered not only the stream flow regime but also the water balance of the region. Alteration of flow regime and quality of lake water, a common problem faced everywhere, arising from increase in demand and developmental activities, is resulting in the hampering of activities supported by these lakes. There are also side effects of ecological imbalances in the region. Impact of degradation is less in the initial stage but the cumulative impact in longer period proves to be deleterious. In many cases, if the state of the problems and their remedial measures is not looked into, it would be difficult to save the lakes and therefore, the adjoining area from economical, hydrological, and environmental disasters.

In national perspective, the most important ecological problems connected with lakes are:

1. Lowering of level due to over use of water as a result of decreasing rainfall in the catchment
2. Rapid siltation caused by accelerated soil erosion
3. Pesticides and toxic chemicals being brought through surface water inflow
4. Eutrophication
5. Disintegration of aquatic system

Problems of Indian lakes

During recent years, due to alteration of landscape by denuding forests, urbanization including tourism and waste discharge into the lakes, sedimentation and consequent eutrophication have increased. Even many high-altitude lakes in Kashmir and in Garhwal Himalayas, which have remained clean and without eutrophication for centuries, are showing signs of deterioration. The famous Dal Lake in Kashmir, which was about 40 km^2 in the beginning of nineteenth century, is presently at about 20 km^2 . Almost half of Lake Renuka (water spread of 670 ha), the biggest lake in the Himachal Pradesh in lower Siwaliks of Himalayan region, is filled up with sediment. Upper Lake in Bhopal, Poondi, Red Hills in Madras, and Osmansagar in Hyderabad, sources of drinking water for these cities, have shrunk considerably in the recent past causing hardships. In many cases, lakes of smaller sizes in the urban areas are used for dumping of solid and liquid wastes, due to which the thermal regime of the lake has changed. As a result, smaller lakes in India are experiencing the problem of eutrophication and facing untimely death. Occurrence of inorganic nutrients in water and the resulting increase in vegetative productivity has become a serious water quality consideration in the country.

Indian Lakes, Table 1 Statistics of Indian lakes

Lakes in Northern India

Lake	Dal lake in Srinagar, Jammu and Kashmir
Location	In the heart of city, Srinagar, State – Jammu and Kashmir, India
Location on map	34°07'N 74°52'E
Climate	Arid cold climate. It receives an average annual rainfall of 655 mm (25.8 in.) in the catchment, but during the summer, snow melt from the higher ranges of the catchment results in large inflows into the lake.
Altitude	1,587 m above mean sea level in the flood plain of river Jhelum in the eastern part of Srinagar city at the foot of Zabaravan mountains
Surface area	18–22 km ² (6.9–8.5 miles ²). Max. length 7.44 km (4.62 miles) Max. width 3.5 km (2.2 miles) Average depth 1.42 m (4.7 ft) Max. depth 6 m (20 ft) Water volume 983 MCM Residence time 22.16 days Shore length 15.5 km (9.6 miles) Surface elevation 1,583 m (5,194 ft) Catchment area 316 km ² (122 miles ²)
Inflow	Eighty percent of the inflow to the lake is supplied through the Telbal Nallah and 20% through direct precipitation. The maximum flood discharge of Telbal Nallah has been assessed as 141.5 m ³ /s for a 1 in 100 return period; the 1973 observed flood in Telbal Nallah has been estimated as 113 m ³ /s. The average annual flow, according to discharge measurements, has been estimated as 291.9 million cubic meters (MCM). Spring sources also contribute to the flow, although no specific data is available to quantify their contribution.
Outflow	There are two outlets from the lake, namely, the Dalgate and Amir Khan Nallah that connects the lakes of Nagin and Anchar. Dalgate is controlled by a weir and lock system. The outflow from these two outlets has been estimated as 275.6 MCM. Further, the silt load has been estimated at 80,000 t per year with 70% contribution from the Telbal Nallah, with 36,000 t recorded as settling in the lake. A small canal connects Dal lake with the Anchor lake and acts as an additional outflow channel.
Type of lakes	A natural freshwater lake, Warm monomictic. Frozen during severe winter. There are two islands (Sona Lank and Rupa Lank (or Char Chinari)) in the lake.
Ecological status	The ecosystem of Dal lake is ecologically rich in macrophytes, submerged macrophytes, floating macrophytes, and phytoplankton. Macrophyte flora recorded in the lake's aquatic and marshland environment consists of 117 species, belonging to 69 genera and 42 families. The lake is noted in particular for its <i>Nelumbo nucifera</i> (lotus flowers) which bloom in July and August. The prolific growth of <i>Ceratophyllum demersum</i> in the eutrophic zones has been reported, with <i>Myriophyllum spicatum</i> and <i>Potamogeton lucens</i> cited as dominant species. Other macrophytes discerned in different zones of the lake include <i>Typha angustata</i> , <i>Phragmites australis</i> , <i>Myriophyllum</i> , <i>Sparganium erectum</i> , and <i>Myriophyllum verticillatum</i> , which contribute to the production of macrophytes. The rooted variety of the floating leaf type consists of <i>Nelumbium nucifera</i> , <i>Nymphaea alba</i> , <i>N. Tertagonia</i> , <i>N. Candida</i> , <i>Nymphoides peltatum</i> , <i>Salvinia natans</i> , <i>Hydrocharis dubia</i> , <i>Nymphaea</i> sp., and <i>Potamogeton natans</i> , all of which occupy 29.2% of the lake. Phytoplanktons include <i>Navicula radiosa</i> , <i>Nitzschia acicularis</i> , <i>Fragilaria crotonensis</i> , <i>Diatoma elongatum</i> , <i>Scenedesmus bijuga</i> , <i>Pediastrum duplex</i> , <i>Tetraedron minimum</i> , <i>Microcystis aeruginosa</i> , and <i>Merismopedia elegans</i> . Woody vegetation in the catchment of the lake consists of <i>Melia</i> , <i>Ailanthus</i> , <i>Robinia</i> , <i>Daphne</i> , <i>Celtis</i> , <i>Rose</i> , <i>Ephedra</i> , <i>Pinus roxburghii</i> , <i>Pinus halepensis</i> , <i>Pinus gerardiana</i> , <i>Cupressus torulosa</i> , and <i>Cupressus arizonica</i> . The valley also has a rich cultivation of crops such as paddy, wheat, and fodder.
Changes over the last years	The lake has been extensively reclaimed to form man-made islands separated by canals and areas of water covered by floating gardens. Total water spread area of the lake has shrunk to 12.4 km ² from 23.4 km ² in 120 years. The shrinkage is attributed to heavy siltation and urbanization. Since 1934, some important changes have been observed in the lake's biota, including a reduction in the number of Charaspecies, and an increase in the area covered by <i>Salvinia</i> since 1937. Analysis of the lake has also revealed the tendency for it to develop monospecific communities of submerged macrophytes such as <i>Ceratophyllum</i> and <i>Myriophyllum</i> .
Biodiversity	The lake is shrinking due to deposits of large quantities of silts being dumped into the lake by Telbal Nallah. The faunal distribution consists of Zooplanktons, Benthos, and Fish. Zooplanktons found in the lake include <i>Keratella cochlearis</i> , <i>K. serrulata</i> , <i>Polyactis vulgaris</i> , <i>Brachionus plicatilis</i> , <i>Monostyla bulla</i> , <i>Alona monocantha</i> , <i>Cyclops ladakanus</i> , and <i>Mesocyclops leuckarti</i> . Benthos include <i>Chironomus</i> sp. and <i>Tubifex</i> sp. and fish include <i>Cyprinus carpio specularis</i> (economically important), <i>C. carpio communis</i> , <i>Schizothorax niger</i> , <i>S. esocinus</i> , <i>S. curvifrons</i> , and <i>Crossocheilus latius</i> . It is also reported that <i>Cyprinus</i> , introduced during the early 1960s, is dominant and that the indigenous species of the genus <i>Schizothorax</i> is showing a declining trend.

Indian Lakes, Table 1 (Continued)

Recreation	It is a major center of tourism. Floating gardens, labeled the “Rad” in the Kashmiri language, are a special feature of the lake. They basically constitute of matted vegetation and earth, but are floating. These are detached from the bottom of the lake and drawn to a suitable place (generally to the northwest of the houseboats’ location) and anchored. Given its rich nutrient properties, tomatoes, cucumbers, and melons are grown with noteworthy results.
Commercial use	The fishing industry on Dal lake is the second largest industry in the region and is central to many of the people’s livelihoods who reside on the lake’s periphery. Dal lake’s commercial fisheries are particularly reliant on carp fish species, which were introduced into the lake in 1957. As a result, carp constitutes 70% of all the fish caught in the lake while the <i>Schizothorax</i> constitutes 20% and other species account for 10%. Fishermen use a locally manufactured cast net which comprises six parts with a diameter of 6 m. It is operated from a wooden fishing boat made out of deodar, typically 20 ft × 4 ft in size. The gradual decline in quality of the lake water through pollution has resulted in lower fish stocks and the extinction of endemic varieties of fish. The causes for such deterioration have been identified and remedial actions have been initiated.
Studies undertaken	Considerable study had been carried out on the limnological, ecological, environmental, eutrophication, and siltation problems of the lake. Bathymetric survey was first introduced in 1976 in the lake study for Dal lake. Studies of the water quality of the lake in 1983–1984 indicate a decline in quality since the 1965–1966 analysis. Scientific researches over the years also reveal that Telbal, Botkal, and sewage drains are responsible for a substantial influx of nitrogen and phosphorus into the lake. Quantitatively, 15 drains and several other sources have released a total of 156.62 t (56.36 t by drains alone) of phosphorus, and 241.18 t of inorganic nitrogen into the lake from a discharge of 11.701 MCM/year. Nonpoint sources, such as seepage and diffused runoff, also add to this pollution and have been recorded as further adding 4.5 t of total phosphates and 18.14 t of nitrogen (NO ₃ —N and NH ₄ —N) to the lake. Based on the values mentioned above, it has been inferred that the water quality of the lake has deteriorated. The lake is warm monomictic (mixing type) and the pH value recorded has varied from a minimum of 7.2 to a maximum of 8.8 on the surface over a yearly period. The Dissolved oxygen (mg l ⁻¹) value has varied from a minimum of 1.4 to a maximum of 12.3 on the surface within a year. The recorded maximum nitrogen concentration (NH ₄ -N [micro l—l]) has been recorded as 1,315 on the surface and 22 at the bottom of the lake. Phosphorus concentration expressed in Total-P (micro l—l) has varied from a high of 577 to a low of 35 during the 12 months of the year. The lake water temperature has varied from a minimum of 3°C (37°F) in January to a maximum of 26°C (79°F) in June at the surface. Transparency, expressed as depth in meters, has varied from a maximum of 1.95 m (6.4 ft) in July to a minimum of 0.53 m (1.7 ft) in March, over the 12 months period.
Governing authority General	Dal lake Development Authority, Srinagar, Jammu and Kashmir The major environmental problem facing the lake is eutrophication, which has required immediate remedial measures to combat it. Alarming, the size of the lake has shrunk from its original area of 22 km ² (8.5 miles ²) to the present area of 18 km ² (6.9 miles ²), and there is a concerning rate of sediment deposition due to catchment area degradation. The water quality has also deteriorated due to intense pollution caused by the untreated sewage and solid waste that is fed into the lake from the peripheral areas and from the settlements and houseboats. Encroachments of water channels and consequent clogging have diminished the circulation and inflows into the lake; so with the building up of phosphates and nitrogen, this has led to extensive weed growth and consequences on the biodiversity of the lake.
Lake	Wular lake in Jammu and Kashmir
Location	In Bandipore district of Jammu and Kashmir
Location on map	34 20’N 74 36’E
Climate	The catchment area has a warm, dry summer and cold, wet winter. It receives an average annual rainfall of 700 mm in the catchment, but during the summer, snow melt from the higher ranges of the catchment results in large inflows into the river and the lake.
Altitude	1,580 m above mean sea level in the flood plain of river Jhelum.
Surface area	The lake’s size varies from 12 to 100 miles ² (30–260 km ²), depending on the season. Presently maximum depth of the lake is about 40 m. Maximum depth of lake has reduced to 40 m from about 100 m in the last 200 years.
Inflow	Fed by the Jhelum River.
Outflow	Outflow from the lake again goes to Jhelum River
Type of lakes	Wular lake is a large freshwater natural lake. The lake basin was formed as a result of tectonic activity.
Ecological status	The lake is 1 of 6 Indian wetlands designated as a Ramsa Site. However, it faces environmental threats including the conversion of large parts of the lake’s catchment areas into agricultural land, pollution from fertilizers and animal wastes, hunting of waterfowl and migratory birds, and weed infestation in the lake itself.

Indian Lakes, Table 1 (Continued)

Changes over the last years	In ancient times, Wular lake was also called “Mahapadamsar.” Nilamata Purana also mentions it as “Mahapadmasaras.” Mahapadamsar is referred as Bolor by Al-Biruni (AD 960–1031). The lake, with its big dimensions and the extent of water, gives rise to high leaping waves in the afternoons, called Ullola in Sanskrit, meaning stormy leaping, high rising waves. Therefore, it was also being called “Ullola.” Its corrupted form saw its transition as “Bolor” by Al-Biruni and over the centuries corrupted further to “Wulor” or “Wular.” The origin may also be attributed to a Kashmiri word “Wul,” which means a gap or a fissure, appellation that must have come also during this period. The word Wul (Gap or fissure) is also an indicator of its origin to a fissure or gap created.
Biodiversity	Wular lake is an important fish habitat, the main species being the common carp (<i>Cyprinus carpio</i>), rosy barb (<i>Barbus conchontius</i>), mosquitofish (<i>Gambusia affinis</i>), <i>Nemacheilus</i> species, <i>Crossocheilus latius</i> , and various snowtrout (disambiguation needed) species in the genera <i>Schizopyge</i> and <i>Schizothorax</i> . Snowtrout species identified in the lake include the Sattar snowtrout (<i>Schizopyge curvifrons</i>), Chirruh snowtrout (<i>Schizopyge esocinus</i>), <i>Schizothorax planifrons</i> , <i>Schizothorax macropogon</i> , <i>Schizothorax longipinus</i> , and Chush snowtrout (<i>Schizopyge niger</i>). Fish from Wular lake make up a significant part of the diet for many thousands of people living on its shores and elsewhere in the Kashmir valley. More than 8,000 fishermen earn their livelihood from the lake, primarily fishing for the endemic <i>Schizothorax</i> species and the nonnative carp. Their catch comprises about 60% of the total yield of fish in Kashmir. Hundreds of other local villagers are employed by cooperative societies that trade the fish catch. Many other families harvest plants such as the grass <i>Phragmites</i> and the waterlily-like <i>Nymphoides</i> from the lake for animal fodder. The lake sustains a rich population of birds. Terrestrial birds observed around the lake include the black-eared kite, sparrow hawk (disambiguation needed), short-toed eagle, Himalayan golden eagle, monal pheasant, chukar partridge, koklass pheasant, blue rock pigeon, cuckoo, small cuckoo, alpine swift, Kashmir roller, Himalayan Woodpecker, hoopoe, common swallow, golden oriole, and others.
Recreation	The Kashmiri sultan Zain-ul-Abidin is reputed to have ordered the construction of the artificial island of Zaina Lank in the middle of the lake in 1444.
Commercial use	The Tulbul Project is a “navigation lock-cum-control structure” at the mouth of Wular lake. According to the original Indian plan, the barrage was expected to be of 439-ft long and 40-ft wide, and would have a maximum storage capacity of 0.30 million acre-feet of water. One aim was to regulate the release of water from the natural storage in the lake to maintain a minimum draught of 4.5 ft in the river up to Baramulla during the lean winter months. The project was conceived in the early 1980s and work began in 1984. There has been an ongoing dispute between India and Pakistan over the Tulbul Project since 1987, when Pakistan objected that it violated the 1960 Indus Water Treaty. India stopped work on the project that year, but has since pressed to restart construction. The Jhelum River through the Kashmir valley below Wular lake provides an important means of transport for goods and people. To sustain navigation throughout the year a minimum depth of water is needed. India contends that this makes development of the Tulbul Project permissible under the treaty, while Pakistan maintains that the project is a violation of the treaty. India says suspension of work is harming the interests of people of Jammu and Kashmir and also depriving the people of Pakistan of irrigation and power benefits that may accrue from regulated water releases.
Studies undertaken	Limnological studies
Governing authority	Government of Jammu and Kashmir
Lake	Haigam Rakh in Jammu and Kashmir
Location	Situated at 30 km north west of Srinagar
Location on map	34°15'N 74°31'E
Climate	The summer climate is warm and dry and the winter is cold and wet. The average annual rainfall is 850 mm
Altitude	1,580 m above mean sea level.
Surface area	Water spread area of the lake is 1,400 ha. Maximum depth of water in the lake is 1.25 m.
Inflow	From the catchment area
Outflow	There is no outflow from the lake.
Type of lakes	A small freshwater lake on the flood plains of Jhelum.
Ecological status	The rate of siltation and eutrophication in the lake are high. The lake is covered with dense red weed.
Changes over the last years	Lake is shrinking due to siltation from all around the lake.
Commercial use	For tourism purpose.

Indian Lakes, Table 1 (Continued)

Studies undertaken	Limnological and biological study. Study on mineral composition, bio-geochemical cycling, plankton population, biomass productivity, trophic structure, and plant community architectures. The Bombay Natural Society had worked on flora and fauna of the lake. The Department of Wild Life Protection had conducted some waterfowl census and two Oxford University Expeditions had studied the breeding birds and passage migrants.
Governing authority	Government of Jammu and Kashmir
Lake	Mansar lake, Jammu and Kashmir
Location	62 km (36 miles) from Jammu
Location on map	34°14'–35°01'N ; 74°40'–74°43'E
Climate	The summer climate is warm and dry and the winter is cold and wet. The average annual rainfall is 800 mm
Altitude	2,000 m above mean sea level.
Surface area	Over a mile in length by half-a-mile in width.
Inflow	From the catchment area
Outflow	Through underground channels
Type of lakes	Mansar is a beautiful lake fringed by forest-covered hills
Ecological status	The lake is still fresh but showing sign of eutrophication.
Changes over the last years	The lake is shrinking due to boulders being brought by snow melt. The tourists visiting the lake spill waste around the lake due to which it is getting polluted.
Biodiversity	With all religions' belief and heritage behind, the Mansar lake is also picking up its fame among the tourists with all its flora and fauna. The lake has cemented path all around with required illumination, with projected view decks to enjoy flickering of seasonal birds, tortoise, and fishes of different species. There is a wild life sanctuary housing jungle life like Spotted Deer, Neelgai, etc., besides other water birds such as Cranes, Ducks, etc. One can also witness the traditional and typical distinct life style of Gujjar and Backarwals wearing ethnic costume, living in open Kullhas around on the hills of Mansar lake.
Recreation	Besides being a popular excursion destination in Jammu, it is also a holy site, sharing the legend and sanctity of lake Mansarovar. On the Eastern Bank of the lake there is a shrine to Sheshnag, a mythological snake with six heads. The shrine comprises a big boulder on which are placed a number of iron chains perhaps representing the small serpents waiting on the tutelary deity of the Sheshnag. Two ancient temples of Umapati Mahadev and Narsimha and also a temple of Durga are situated in the vicinity of the Mansar lake. People take a holy dip in the water of the lake on festive occasions.
Commercial use	Newly weds consider it auspicious to perform three circum-ambulations (Parikarma) around the lake to seek the blessings of Sheshnag, the Lord of serpents, whose shrine is located on its eastern bank. Certain communities of Hindus perform the Mundan ceremony (First hair cut) of their male children here. There are also some ancient temples on the lake's shores, which are visited by devotees in large numbers. Mansar is also ideal for boating for which the Tourism Department provides adequate facilities. This Mansar lake road joins to another important road that directly links Pathankot (Punjab) to Udhampur (Jammu and Kashmir, Jammu Province). Udhampur is a town of strategic importance, again on National Highway No. 1A.
Studies undertaken	Hydrological studies have been undertaken by National Institute of Hydrology, Roorkee.
Governing authority	Government of Jammu and Kashmir, India
Lake	Nainital lake in Uttarakhand (Erstwhile Uttaranchal)
Location	In the heart of Nainital in Uttarakhand State of India
Location on map	29°24'N 79°28'E/29.4°N 79.47°E
Climate	The annual rainfall in the basin area of the lake is 1,294.5 mm (43.15 in.). Tropical monsoon climate with maximum temperature 24.6°C and minimum of 0.5°C.
Altitude	1,937 m above mean sea level
Surface area	The lake area is about 5.85 km ² . The areal extent of the lake is also reducing. Maximum depth of lake has reduced from 27.45 m in 1950 to about 24 m in 1980. Max. length 1,432 m (4,698 ft) Max. width 42 m (138 ft) Surface area 48.76 ha (120.5 acres) Max. depth 27.3 m (90 ft) Residence time 1.16 years Surface elevation 1,938 m (6,358 ft)
Inflow	The lake receives flows from the surrounding catchment basin which comprises the hill slopes and springs.
Outflow	Has an outfall at the south-eastern end. The components of outflows were the surface outflow, the subsurface outflow through the springs on the downstream side and draft through wells for meeting the water supply of Nainital town and evaporation loss from the lake surface.

Indian Lakes, Table 1 (Continued)

Type of lakes	A freshwater lake. There is a submerged island running across center of the lake dividing it into two basins. Tectonic in origin, is kidney shaped or crescent shaped.
Ecological status	The lake is bounded by the high and steep Naina peak on the northwest side, by the Tiffin Top to the southwest side and snow view peaks on the north. Coniferous forest trees cover these hill ranges.
Changes over the last years	Deforestation of the surrounding hills is causing landslide due to which heavy load of boulders and sediment get dumped in the lake from time to time. Lake capacity is reducing
Biodiversity	The Nainital district, where the lake is situated (in the middle Himalayan ranges up to 2,000 m (6,600 ft), a temperate zone), is rich in flora (typical temperate climate plants) and fauna. Vegetation: The trees and bushes grown in the region (lake's basin) with their botanical and common Indian names (in parenthesis) are reported to be: (a) <i>Quercus incana</i> (Oak [Banj]); (b) <i>Aesculus indica</i> (Pangar or Horse chestnuts); (c) <i>Juglans regia</i> (Akhrot or walnut); (d) <i>Populus ciliata</i> (Hill Pipal, a sacred tree); (e) <i>Fraxinus micrantha</i> (Ash tree or Angu); (f) <i>Platanus orientalis</i> (Chinar); (g) <i>Rubus lasiocarpus</i> (Himalu); (h) <i>Rosa moschata</i> (Kunj or Musk rose); (i) <i>Berberis asiatica</i> (Kilmora); (j) <i>Cupressus torulosa</i> (Surai or Himalayan cypress); (k) <i>Rhododendron arboreum</i> (Buruns), <i>Cedrus deodara</i> (Deodar); (l) <i>Salix acmophylla</i> (Weeping Willow); and (m) <i>Pinus</i> (Pine). The aquatic macrophytic vegetations recorded are (1) <i>Potamogeton pectinatus</i>, (2) <i>Potamogeton crispus</i>, (3) <i>Polygonum glabrum</i>, (4) <i>Polygonum amphibium</i>, and (5) <i>Polygonum hydropiper</i> (Water pepper). Several species of medicinal flora and horticulture plants have also been reported. Aqua fauna: The fishes found in the lake are generally carps mahseer, (the Hindi name of mahāsir, mahāser, or mahāsaulā used for a number of fishes of the group), also hill trout and the mirror carp which breed several times during one spawning season during May to September. Two species of Mahaseer fish, viz., <i>Tor tor</i>: The red finned mahseer and the <i>Tor putitora</i>: The yellow finned mahseer, a food fish which grows to varying sizes from 20 to 60 cm (7.87–23.62 in.) are reported. The three species of hill trout found in the lake are the <i>Schizothorax sinuatus</i>, <i>Schizothorax richardsoni</i>, and <i>Schizothorax plagiostomus</i>. The imported fish bred in the lake is Mirror carp or <i>Cyprinus carpio</i>. <i>Gambusia affinis</i> also called Mosquitofish have been introduced in the lake as a biocontrol measure to control mosquito larvae. Fauna: Nine species of birds and nine species of animals have been recorded in the Nainital district.
Recreation	There is the Nainital Boat Club that offers yachting facilities at the lake. The Annual Kingfisher Yachting Competition (Regatta) is held here in the third week of June. The Kumaun Festival, exhibiting local cultures and traditions, is organized by the Tourism Department every year during the winter months of October and November.
Commercial use	The lake is the epicenter of tourism in Uttarakhand.
Studies undertaken	Several limnological and hydrological studies have been undertaken. The water is reported to be alkaline in nature (ph value of 8.4–9.3). The hydrologic studies related to water balance and sedimentation were done using radioisotopes for estimating/measuring the various components of the inflow and outflow into the lake. Studies indicated that the subsurface inflow and outflow were significant – ranging from 43% to 63% and 41% to 54%, respectively, of the total inflow and outflow, except in years of exceptionally heavy rainfall. The mean water retention time for the lake was computed as 1.16 years for the mean annual rainfall. A scientific study indicates that the open drains feeding the lake introduce toxic substances from the catchment of the lake, particularly heavy metals which get adsorbed onto the suspended sediments, which in turn settle down in the bottom of the lake. A study of the risk assessment code has revealed that 4–13% of manganese, 4–8% of copper, 17–24% of nickel, 3–5% of chromium, 13–26% of lead, 14–23% of cadmium, and 2–3% of zinc exist in exchangeable fraction which puts the lake under the low-to-medium risk category and infers that it could enter into food chain and also cause deleterious effects to aquatic life. This study provides the basic database to formulate guidelines for the dredging operations and/or restoration programs in the lake. The water quality studies carried out by the National Institute of Hydrology during 1999–2001 on physicochemical parameters (pH, temperature profile, Secchi's transparency, dissolved oxygen, BOD, COD, and nutrients), biological profile (density of population, biomass and species diversity of phyto, zooplankton and macrobenthos), and bacteriological characteristics have led to the conclusion that long-term limnological changes have occurred in the lake. Excess of nutrients inflow have contributed to the eutrophic conditions and the internal recycling of nutrients from sediments during water circulation has resulted in luxurious growth of phytoplankton. The lake is thus anoxic and has reduced hypolimnion, winter circulation, large phytoplankton, and relatively lower animal population.

Indian Lakes, Table 1 (Continued)

Governing authority
General

Nainital Lake Development Authority

Lake Restoration

The National Institute of Hydrology (NIH) of Roorkee, India, who prepared a plan for the restoration of the lake, at an estimated cost of Rs. 50 crore (about US\$10 million), sponsored by the Ministry of Environment and Forests, Government of India, is also now guiding the restoration measures. The Conservation and Management Plan evolved by NIH is not only lake centric but also proposes to tackle the immediate periphery of the lake which contributes an adverse impact on the lake. The "Nainital Jheel Parikshetra Vishesh Kshetra Vikas Pradhikaran," the Lake Development Authority notified under U.P. Special Area Development Act 1986 is a Special Purpose Vehicle (SPV) set up for implementing the restoration works. The restoration works that have been implemented or are in different stages of implementation are the following:

Limnological measures such as controlled aeration of hypolimnetic water, siphoning of hypolimnetic water, biomanipulation and limited sediment removal from the deltas of drains which lead to the lake.

Soil Conservation and Slope Stabilization measures in the form of soil conservation and watershed management activities in the catchment area of the lake, slope stabilization, Drainage line treatment, landslide scars to be treated with Coir geotextiles with gabion cross-barriers and proper maintenance and cleaning of drainage system.

Provide 100% coverage of the town surrounding the lake with sewers and Sewage Treatment Plants (STPs).

Improved sanitation around the lake and in the catchment with new community toilets to cover all sections of the society, improved design of household toilets.

Better solid waste management by disposing solid waste through a chute to the downhill outside the catchment, developing landfill sites in isolated habitations in the upper reaches of hills, and introducing composting measures with support from NGOs.

Limited dredging of the lake, particularly near the deltas of drains that bring sediments.

Fish *Gambusia affinis* introduced a few years ago to control mosquito larvae, the fish have started feeding on the larger zooplankton resulting due to scanty larvae population resulting in adverse impact on the lake water quality. This needs to be controlled by putting minnow traps in the lake and introducing some other fish species.

The outflow from the lake is into the Balia Nala drain controlled by a set of sluices located at the lake bridge. The sluices which are old need renovation and replacement. The Balia Nala also needs slope stabilization measures to check landslides.

Shoreline Development and improvement of facilities at all important monuments and temples located in the periphery of the lake and providing avenue paths and roads.

Improved public awareness and public participation programs.

The "Nainital Jheel Parikshetra Vishesh Kshetra Vikas Pradhikaran" could function better in a limited role as a promoter and a facilitator for developmental and commercial activities with jurisdiction extended to cover all four lakes in the district, as at present a plethora of organizations are functioning in the notified area such as Nainital Nagar Palika Parishad, Jal Nigam, Irrigation Department, Power Corporation, Forest Department, and Fisheries Department who are directly involved with the lake.

The Honorable Supreme Court of India in its judgment of 1995, in response to the Public Interest Litigation, gave the following recommendations which have also been addressed in the restoration measures mentioned above.

- (1) Sewage water has to be prevented at any cost from entering the lake; (2) So far as the drains which ultimately fall in the lake are concerned, it has to be seen that building materials are not allowed to be heaped on the drains to prevent siltation of the lake; (3) Care has been taken to see that horse dung does not reach the lake. If for this purpose the horse stable has to be shifted somewhere, the same would be done. The authorities would examine whether trotting of horses around the lake is also required to be prevented; (4) Multi-storied group housing and commercial complexes have to be banned in the town area of Naini Tal. Building of small residential houses on flat areas could, however, be permitted; (5) The offence of illegal felling of trees is required to be made cognizable; (6) Vehicular traffic on the Mall has to be reduced. Heavy vehicles may not be permitted to ply on Mall; and (7) The fragile nature of Ballia Ravine has to be taken care of. The cracks in the revetment of Ballia Nullah have to be repaired urgently.

In his article, "Lady of the Lake" in *India Today* (India Today, 2001), S. Prasannarajan, a journalist, has very vividly described the lake in these words in a preamble to the particular interest shown by Aradhana Shukla, The Lady District Magistrate of Nainital in restoration works of the lake:

Look for the lake through the colonial windows of Pant House, a vintage English bungalow on the hilltop, now submerged in wintry night, solitary with a kind of Wuthering Heights mystery. Down below, the lake is a laminated stillness, protected by seven never-sleeping hills. In the dead darkness of Kumaon, this magnificence is a distant, partially lit vision, less than real, as the hills of frozen memories make the lake a footnote in water.

Indian Lakes, Table 1 (Continued)

Lake	Naukuchiatal lake in Uttarakhand
Location	Situated at a distance of 5 km from Bhimtal lake in Nainital district of Uttarakhand.
Location on map	29°32'N 79°21'E.
Climate	The annual rainfall in the basin area of the lake is 1,200 mm. Tropical monsoon climate with maximum temperature 24.6°C and minimum of 0.5°C.
Altitude	1,320 m above mean sea level.
Surface area	It has an irregular shape. The maximum aerial extent of the lake is 90 ha. Lake basin is a conical deep trough with flat bottom. Basin walls have steep slope. Mean depth of the lake is about 21.89 m. Maximum depth of the lake is 41.25 m.
Inflow	From Nainital lake
Outflow	It has a small artificial outlet leading to Bhimtal Gadhera
Type of lakes	Naukuchiatal lake is the deepest and most voluminous of the Kumaun lakes of the lesser Himalayas.
Ecological status	North west corner of the lake is a delatic plain which is marshy and swampy. To the north west of the lake is the Nal-Damayanti lake which was previously a lake, is now in the form of a tank.
Changes over the last years	The lake is facing a threat not only to the quality of its water but to its mere existence too, from the rapid growth of the human activities, not only in catchment area but even in basin area of the lake.
Biodiversity	Vegetation: The trees and bushes grown in the region (lake's basin) with their botanical and common Indian names (in parenthesis) are reported to be: (a) <i>Quercus incana</i> (Oak [Banj]); (b) <i>Aesculus indica</i> (Pangar or Horse chestnuts); (c) <i>Juglans regia</i> (Akhrot or walnut); (d) <i>Populus ciliata</i> (Hill Pipal, a sacred tree); (e) <i>Fraxinus micrantha</i> (Ash tree or Angu); (f) <i>Platanus orientalis</i> (Chinar); (g) <i>Rubus lasiocarpus</i> (Hisalu); (h) <i>Rosa moschata</i> (Kunj or Musk rose); (i) <i>Berberis asiatica</i> (Kilmora); (j) <i>Cupressus torulosa</i> (Surai or Himalayan cypress); (k) <i>Rhododendron arboreum</i> (Buruns), <i>Cedrus deodara</i> (Deodar); (l) <i>Salix acmophylla</i> (Weeping Willow); and (m) <i>Pinus</i> (Pine). Several species of medicinal flora and horticulture plants have also been reported. Aqua fauna: The fishes found in the lake are generally carps mahseer, (the Hindi name of mahāsir, mahāser, or mahāsaulā used for a number of fishes of the group), also hill trout and the mirror carp which breed several times during one spawning season during May to September. Two species of Mahaseer fish, viz., Tor tor: The red finned mahseer and the Tor putitora: The yellow finned mahseer, a food fish which grows to varying sizes from 20 to 60 cm (7.87–23.62 in.) are reported. The three species of Hill Trout found in the lake are the <i>Schizothorax sinuatus</i> , <i>Schizothorax richardsoni</i> , and <i>Schizothorax plagiotormus</i> . The imported fish bred in the lake is Mirror carp or <i>Cyprinus carpio</i> . <i>Gambusia affinis</i> also called Mosquitofish have been introduced in the lake as a biocontrol measure to control Mosquito larvae. Fauna: Nine species of birds and nine species of animals have been recorded in the Nainital district.
Recreation	For tourism
Commercial use	The lake water is excessively used for irrigation and drinking purposes in the lower valley villages.
Studies undertaken	Considerable studies on limnological and ecological aspects of the lake in Kumaun Himalaya. Limnological study was conducted through bathymetric map.
Governing authority	There is no governing authority.
Lake	Bhimtal lake in Uttarakhand
Location	A lake in the town of Bhimtal, Uttarakhand, India.
Location on map	29°20'35"N 79°33'33"E
Climate	The annual rainfall in the basin area of the lake is 1,294.5 mm (43.15 in.). Tropical monsoon climate with maximum temperature 24.6°C and minimum of 0.5°C
Altitude	1,345 m above mean sea level
Surface area	The maximum depth of the lake is 24.75 m and the minimum depth is 12–13 m. The shoreline index is 1.67 and its development index is 1.74. The total volume of the lake is $4,245 \times 10^3 \text{ m}^3$.
Inflow	From the hilly catchment and underground spring
Outflow	There is no outflow from the lake
Type of lakes	The largest among Kumaun lakes. It is a perennial freshwater lake, irregular in shape.
Ecological status	Over the years, the lake has got filled with debris from all over the catchment and infested with planktons
Changes over the last years	The town though ancient was never prominent because of nearby Nainital which was the summer capital of erstwhile United Province of India and contained all the amenities to be found in any European town. But, over time Nainital became crowded and ugly and the lake so polluted that people do not drink directly from it.
Biodiversity	It is a perennial lake which not only supports a large variety of aquatic life but is also a winter stopover for Trans-Himalayan birds.

Indian Lakes, Table 1 (Continued)

Recreation	It is still center of tourism for the district of Kumaun of Uttarakhand.
Commercial use	For tourism
Studies undertaken	Considerable studies on limnological and ecological aspects of the lake in Kumaun Himalaya. Limnological study was conducted through bathymetric map.
Governing authority	State Government of Uttarakhand.
Lake	Renuka lake in Himachal Pradesh
Location	173 km south west of Shimla, in Sirmur district of Himachal Pradesh, India
Location on map	30°36'36"N 77°27'30"E
Climate	Subtropical monsoon climate. Average annual rainfall in catchment area of the lake is 1,500 mm.
Altitude	700 m above mean sea level
Surface area	Catchment area of 254.3 km ² is in hilly forested terrain. It is the largest lake in Himachal Pradesh, with a circumference of about 3,214 m.
Inflow	The lake is fed by monsoon runoff from the catchment area and perennial underground seepage water.
Outflow	There is no outflow from the lake.
Type of lakes	A natural, low-altitude freshwater lake. It is a long, narrow, oblong-shaped lake flanked by two parallel steep hills running east–west.
Ecological status	A total catchment area of 90% is under the subtropical deciduous reserve forest cover. The lake is threatened by continuously shrinking size. The silt which gets deposited in the lake is causing a major concern to the locals and the administration. The main cause of this is the soil being deposited on the banks, with the rainwater and land slides in the nearby mountains. Also the waste of construction material is being dumped into the lake for years, which is a big threat to the environment. Administration and Renuka Vikas Smiti is trying its best to protect the lake. The plastic bags are banned in the entire region.
Changes over the last years	If corrective measures are not taken to save the lake in a timely manner, it will effect environment and also the business of the locals, which depends upon the Tourism, attracted by the lake. The most loving and important thing is the behavior of small children in that local area; they are quietly adjoining their hands and saying “Namaste” (giving respect and making welcome) to any newer person and tourist. Presently length of the lake is about 1.5 km, breadth is about 0.3 km, maximum depth of water in the lake is about 10.0 m, and minimum depth of water in the lake is about 5.0 m. The lake is fast shrinking. Maximum depth is presently only 10 m which was up to 25 m in the last decade.
Biodiversity	• The lake is monolithic with distinct stratification during May–October. Overturning of lake water takes place. • One fourth of the lake area is covered by marshes. • Freshwater fish habitat used to be in abundance is now decreasing.
	<i>Renuka Sanctuary</i>
	The sanctuary is situated in Sirmour district in Himachal Pradesh. The sanctuary is well connected by the network of motorable roads. The total area of the sanctuary is about 4.028 km ² . The entire sanctuary consists of Renuka Reserve Forest and has been declared as Abhayaranya. An area of roughly about 3 km ² that lies outside the sanctuary has been declared as a buffer belt. The sanctuary falls in the biogeographical zone IV and biogeographical province IV as per the classification done by the Wildlife Institute of India (WII). According to the classification of the types of forest, the area falls under group 5B/C2, i.e., dry mixed deciduous forest, and group 5/051, i.e., dry sal forest.
Recreation	It is the site of an annual fair held in November.
Commercial use	For tourism
Studies undertaken	Limnological and ecological studies with special reference to its flora and fauna.
Governing authority	Himachal Pradesh State Government
General	Lake was named after the goddess Renuka. It is well connected by the road. Boating is available on the lake.
Lake	Maharana Pratap Sagar in Himachal Pradesh
Location	In Kangra district, Himachal Pradesh
	The closest railway stations to the project are Mukerian 30 km (18.6 miles) and Pathankot 32 km (19.9 miles). Nagrota Surian and Jawali located on the periphery of the reservoir are connected by the narrow gauge railway line, the Kangra railway line, which connects Pathankot to Jogindernagar.
Location on map	32°01'N & 76°05'E
Climate	Subtropical monsoon climate. Average annual rainfall in the catchment area of the lake is 1,500 mm.

Indian Lakes, Table 1 (Continued)

Altitude	Low-altitude reservoir
Surface area	Catchment area of 12,561 km ² . Surface area of the lake varies from 240 to 450 km ² . Maximum length is 42 km and maximum width is 2 km. The reservoir is bounded by the rugged Dhauladhar mountain range, the low foothills of the Himalayas on the northern edge of the Indo-Gangetic plains, and the mountain streams cutting through valleys.
Type of lakes	Named in the honor of the patriot Maharana Pratap (1572–1597), the reservoir or the lake is a well-known wildlife sanctuary and one of the 25 wetland sites declared in India by the Ramsar Convention (Belsare et al., 1990; Cavazza, 1993).
Ecological status	Named in the honor of the patriot Maharana Pratap (1572–1597), the reservoir or the lake is a well-known wildlife sanctuary and one of the 25 wetland sites declared in India by the Ramsar Convention. Pong Dam lake was declared a Ramsar Wetland site on account of its rich waterfowl diversity for conservation and sustainable use of the wetland. This recognition was based on a proposal formulated by the Himachal State Council for Science, Technology and Environment, Shimla, submitted to the Ramsar Bureau, Switzerland through the Union Ministry of Environment and Forests of the Government of India. The large reservoir and its strategic location in the extreme northwest of the northern plains has attracted migratory birds from the plains of India and Central Asian countries and Siberia; more than 220 bird species of 54 families were recorded. The interception of the migratory birds on their trans-Himalayan fly path, during each migration season, has enriched the biodiversity values of the reservoir. The Pando reservoir and its catchment have the following rich flora and fauna.
Biodiversity	The reservoir peripheral land area has mixed perennial and deciduous pine forests on hills. Eucalyptus trees have also been grown in the area. The forest growth provides enough sustenance to the migratory birds. The tree species of the forest area are Acacia, Jamun, Shisham, Mango, Mulberry, Ficus, Kachanar, Amla, and Prunus. A variety of shrubs, grasses, and climbers are also reported. The reservoir seasonal water level variation between the maximum water level and the minimum draw down level does not permit growth of much emergent vegetation but some amount of submerged vegetation is noticed A wide variety of commercially viable fish, 27 species of five families, such as Mahseer, <i>Catla</i> , Mirror Carps, Singhara (native), and others are recorded in the Pong Dam reservoir and its tributaries. Before the reservoir was built, catfishes, mirror carps, and a few coarse fish were the dominant fish fauna in the Beas River. With the emergence of the reservoir, commercial fishing was encouraged as an important program not only to provide employment to about 1,500 fishermen but also to promote the ecotourism potential. A planned operation of fish stocking was launched with first introduction of Common carp in 1974 and Indian major carps or Silver carp in 1976–1977. This resulted in a shift in the catch structure of the reservoir with carps accounting for 61.8% of the total landings in 1987–1988. The present fish stocks in the reservoir, in the sequence of their abundance are: (1) Rohu, <i>Aorichthys seenghala</i> , (2) Labeo calbasu (native), (3) <i>Tor putitora</i> (Himalayan Mahseer), (4) <i>Cirrhinus mrigala</i> , (5) <i>Wallago attu</i> , (6) <i>Cyprinus carpio</i> , (7) Labeo dero, (8) <i>Catla catla</i> , and (9) <i>Channa</i> sp. (MAPCOST Report, 1996). The reservoir, unlike other reservoirs in the region, has shown a marked growth in catch of Mahseer fish recording 20% of the total catch during 1999–2000 with the average size of the fish ranging from 1.5 to 1.7 kg (3.3–3.7 lb). This is attributed to the change in the Himachal Pradesh (HP) Fishing Rules with an added clause which specifies the minimum catchable size for Mahseer as 300–500 mm or approximately 1.2 kg (2.6 lb) which is stated to give to each female Mahseer to breed at least once before being caught. Mahseer angling in the Pong Dam reservoir is said to be the only one of its kind in the country. The reservoir was declared as a bird sanctuary in 1983. A 5 km (3.1 miles) belt from the periphery of the lake has been declared as buffer zone for the management of the bird sanctuary. The national as well as international significance of the sanctuary is enhanced because of its waterfowl diversity, which was evidenced by the increase of waterfowl species from 39 prior to the reservoir to 54 species at post-reservoir stage. The number of birds reported, particularly during the winter period of November to March, has steadily increased over the years and the recent records indicate a waterfowl count of 130,000 in 2004 and 142,000 during 2005 migratory birds – a phenomenal increase from the average annual count of 18,887 for the period 1988–1995. The main bird species reported are the barheaded geese (Goose), Anser indicus, northern lapwing (<i>Vanellus vanellus</i>), ruddy shelduck (<i>Tadorna ferruginea</i>), Northern pintail (<i>Anas acuta</i>), common teal (<i>Anas crecca</i>), Mariana Mallard (<i>Anas poecilorhyncha oustaleti</i>), Eurasian Coot <i>Fulica atra</i> , red-necked Grebe (<i>Podiceps griseigena</i>), Black-headed gulls, plovers, Black Stork, terns, waterfowl, and egrets.

Indian Lakes, Table 1 (Continued)

	The avian habitats in the reservoir area are categorized under the following heads: 1. The receding shoreline forms mudflats and mud spits from October onward which provide organic matter, worms, insects, and molluscs for wintering birds and plovers. Wagtails, Sand Larks, and Pipits also use the mudflats. 2. The shallow water on the margins of the reservoir and the open deep water are used by dabbling ducks (Anatinae) and some long-legged waders. 3. In the sandy banks near the reservoir periphery with dry sand banks strewn with small boulders, with little or no vegetation, stone curlew and pratincoles feed here. 4. Below the outfall of the dam, swamp habitats and water side vegetation are used by birds such as ducks, coot, warblers, babblers, munias, kingfishers, and predators. 5. In the reservoir draw down areas, which are also cultivated by local people during winter, bar-headed geese and ruddy shelduck feed. Around 5,000 tourists visit the bird sanctuary during winter season and most of them come to watch migratory birds for the first time. Efforts are being made to encourage ecotourism to attract more tourists to the reservoir. The periphery above the water surface area of the reservoir has recorded fauna species such as barking deer, sambar, wild boars, leopards, and Oriental Small-clawed Otters.
Recreation	Water sports A regional water sports center has been established in the Pong dam reservoir which offers focused activities such as canoeing, rowing, sailing, and water skiing, apart from swimming. Training programs are organized in water safety and rescue measures with three tier water sports courses – the basic course, intermediate course, and advanced course. Modern infrastructure facilities have been created with a 75-bed hostel and a 10-suit rest house. It is said to be the only center of its type in the country.
Studies undertaken	The following protection measures have enabled preservation of the reservoir ecosystem. • Declaring the entire reservoir as a Wildlife Sanctuary in 1986 by the Himachal Pradesh government has mostly eliminated poaching. Forty Village Forest Development Committees are functioning to prevent poaching of birds, in addition to nine check posts. Two mobile check posts monitor suspicious activities in the sanctuary areas in coordination with the established check posts. This vigilance program has established Nagrota Surian, Guglara, Tairess, Jambal Bassi, Nandpur Bhatoli, and Dehra as dwelling places for the migratory birds. • To check siltation of the reservoir and to provide bird nesting places, plantation of the peripheral area of the lake has been undertaken in a large way. • The Protected Area Management Plan envisages boundary protection, habitat improvement, tourism and regulation, roads and staff quarters, and so forth. • One of the islands in the reservoir has been named Ramsar (after the Ramsar Convention) and developed for nature conservation education, complete with rest house and boating facility. • Organized reservoir fishing with full support of the Department of Fisheries has provided opportunities to reservoir Oustee (project affected people due to submergence) families to take up fishing as a profession. As per the last report, more than 1,789 fishermen are engaged in fishing activities which generate secondary benefits to more than 1,000 families. A large number of Fishermen Cooperative Societies are functioning in the reservoir.
General	Maharana Pratap Sagar, also known as Pong Dam Reservoir or Pong Dam lake, was created in 1975 building the highest earth fill dams in India on the Beas River in the wetland zone of the Siwalik Hills of the Kangara district of the state of Himachal Pradesh in India.
Lake	Prashar lake, Himachal Pradesh
Location	49 km north of Mandi in Mandi District
Location on map	32°41'N & 76°55'E
Climate	Subtropical monsoon climate. Average annual rainfall in catchment area of the lake is 1,800 mm.
Altitude	2,730 m above mean sea level
Inflow	Rainwater, Glacial runoff
Outflow	Evaporation
Type of lakes	Holomictic
Ecological status	With deep blue waters, the lake is held sacred to the sage Prashar and he is regarded to have meditated there. Surrounded by snow-capped peaks and looking down on the fast flowing river Beas, the lake can be approached via Drang.
Biodiversity	The lake has a floating island in it and it is said to be unclear how deep it is, with a diver not being able to determine its depth.
Recreation	Prashar lake is also a symbol of natural beauty which is overlooked by snow-draped peaks and is situated on the highest place of Mandi district. This lake is fed by small mountain streams. From the edge of Prashar lake, tourist can see a slice of the distant snow capped peaks. The water of Sutlej river flowing toward south is also visible. On some special occasions, the neighborhood of this lake doubles as the site for certain festivals too.

Indian Lakes, Table 1 (Continued)

Commercial use	The people of the adjoining area throng this temple during an annual fair held here in the month of June and the village deities of this vast mountainous area are carried to this heavenly spot to pay obeisance to sage Prashar.
Governing authority	Bansen, the king of Mandi, got this temple built in the thirteenth century and the temple is in Pagoda style.
General	With a three-storied pagoda-like temple dedicated to the sage Prashar, it is a center of religious ceremony. The temple was built in the thirteenth century and legend has that it was built by a baby using only a single tree. The whole of the temple is built of a single deodar tree.
Lake	Suraj Tal, Himachal Pradesh
Location	In Lahaul Valley, Himachal Pradesh. Suraj Tal is 65 km from Keylong, the district headquarters of the Lahaul-Spiti district, a frontier district of India which is approachable by road by the National Highway NH 21, also known as the Leh-Manali Highway. The NH 21 is the vital road link for the people living in the Lahaul-Spiti district. The road skirts the Suraj Tal and is just 3 km short of the Bara-lacha-la pass. It remains inaccessible from Rohtang Pass to Leh during winter months of November to April since the pass becomes totally snowbound during this period. “During winters it remains in the grip of a pall of ice untidy with lumps of frozen snow and jutting stones.” But in the summer season this tarn comes back to its glorious charm, the deep blue of its icy waters reflecting craggy mountains and snowy heights.
Location on map	The lake is situated in the Upper Himalayan Zone or High Latitudinal Zone part of the Himalayas which has very sparse population with climatic conditions akin to polar conditions. Snowfall in this zone, though scanty, is reported to be spread all round the year. Rainfall precipitation is rare in the region.
Climate	32°45'N 77°24'E to 32.75°N77°54'E Since the lake is in the valley situated in rain shadow area, north of the Pir Panjal ranges of the Himalayas, the weather remains pleasant and quite comfortable during summers, i.e., from May to mid-October. This is the best season to visit this valley. It seldom rains, and the Mercury level does not exceed 30°C and never falls below 15°C throughout the summer season. One can always enjoy bright sunshine wandering within lush green valley. There is little or no rain in monsoons. The climate remains dry and invigorating. The days are hot and nights are extremely cold. Heavy/Light woollens are recommended. During winter, i.e., from the end of November to April because of western disturbances it snows heavily and the temperature goes down below minus. There is an average annual snowfall of about 200 cm. Rainfall precipitation is rare in the region. Snow precipitation from snow storms is reported to be less than 20 cm (7.9 in.) of snow in nearly 50% of the storms, even though one observatory in the region has reported 80 cm (31.5 in.) of snowfall. The precipitation starts melting from May. Snow on slopes is generally slackly bonded, with wind redistributing it. The average total snowfall recorded in a year is reported to be 12 m (39.4 ft)–15 m (49.2 ft) with temperatures of Highest Max. 13°C (55.4°F), Mean Max. 0.5°C (32.9°F), Mean Minimum minus 11.7°C (53.1°F), and Lowest Minimum of minus 27°C (80.6°F). The ground in the zone is covered with scree and boulders.
Altitude	High-altitude lake, 4,883 m above mean sea level
Surface area	The lake is fed from the glaciers and torrential nullahs (streams) originating from the Bara-lacha-la pass, which is 8 km (5.0 miles) long and is also called the “Pass with crossroads on summit” since roads from Zaskar, Ladakh, Spiti, and Lahaul meet at this pass. In addition to the Suraj Tal and the Bhaga River that originates from it, Bara-lacha-la Pass is also the source of the Chandra and Yunan Rivers in the northwest and north, respectively.
Inflow	Glacier and snow melt
Outflow	Bhaga river
Ecological status	Frozen during winter
Recreation	Lahaul Spiti valley is a common destination for Indian and foreign tourists for road trips, trekking, and motorcycling which cover the lake and the Bara-lacha-la pass, en-route from Manali to Leh. Motorcycle trips during the season when the area is approachable are undertaken by tourists. During such trips from Manali to Leh, the section between Patseo to Bara-lacha-la is a rough journey of 30 km (18.6 miles). Along this route, two small lakes, the Deepak Tal and the Suraj Tal are seen.

Indian Lakes, Table 1 (Continued)

Studies undertaken	Trekking tours are a common feature. One such trek route is the Zingzingbar–Suraj Tal–Bara-lacha-la, which involves trek along the Bhaga River for 3 km (1.9 miles), cross a bridge to the North bank, then a further climb of 2.5 km (1.6 miles) from the bridge followed by a steep foot trail up to Suraj Tal. The lake's geology is represented by the Bara-lacha-la Pass, which is reported to be an early rifting event on the northern Indian passive margin and that the Basalts which are emplaced along the trans-tensional faults indicate that. The Bhaga Valley (Tod or Stod Valley) formed from Suraj Tal up to Tandi, the confluence point with Chandra River, is 64 km (39.8 miles) long (Hoybye, 1997). The valley, which is a narrow gorge, is devoid of any vegetation up to Darcha and thereafter it widens up to its confluence with Chandra River at Tandi with terraces between Darcha and Tandi which are under cultivation in the lower slopes, with the middle slopes having grasslands. Plantation of trees and shrubs to meet fuel wood and fodder requirements has been done on the hill slopes.
General	Patseo and Darcha are the mountain hamlets near the lake.
Lake	Chandra Tal, Himachal Pradesh
Location	Situated in the Spiti district of Himachal Pradesh (India), 6 kms away from the Kunzum Pass in Spiti and Lahaul district of Himachal Pradesh, India.
Location on map	32°28'31"N 77°37'01"E32.47518°N
Climate	The days are not cold but the temperature drops quickly after the sun sets, and the wind adds its bit. The best way to keep warm is to wear clothes in layers
Altitude	4,300 m above mean sea level in the Himalayas
Surface area	Boasting of a circumference of about 2.5 km, the deep blue water of Chandra Tal lake is the source of the Chandra river.
Inflow	The lake is situated on a plateau (Samudra Tapu) overlooking the Chandra River which originates from a glacier near Bara-lacha-la.
Outflow	A clear stream of water flows out of the lake. During the day, the lake appears prussian blue in color, and a greenish tinge appears toward the evening.
Ecological status	The Chandra Tal trek is rated moderate by most people. You can feast your eyes with the unparalleled beauty of this landscape, unique in many respect compared to the other Himalayan treks. The clear blue sky and the rugged brown rolling mountains, almost treeless, form a picture perfect image. This landscape goes on for miles interspersed with lush green meadows, and the sparkling Chandra river down below.
Biodiversity	The mountain peaks with snow caps and slopes around the valley rise up to 3,000–6,300 m. The mountain ranges are called Moukila and Chandrabhaga which challenge mountaineers. This crystal clear blue water lake lies in a broad grassy plain, which in ancient times was a glacier. Ideal for camping, can be approached from Manali and by Kaza.
Recreation	Mountains of scree overlook the lake on one side, and a magnificent cirque presents a view on the other. The name of the lake originates from its crescent shape. Chandra Tal is a popular destination for trekkers and campers. The lake is accessible on foot only for few months in a year, from May to August. Vast meadows are the camping sites on the banks of the enchanting lake. During spring season, it is carpeted with hundreds of kinds of wild flowers.
Commercial use	The Chandra Tal lake, once a halting place for traders who went to Spiti and Kullu valley from Tibet and Ladakh, attract a large number of adventure lovers.
General	From June to September a large number of tourists visit the lake. This is also the time when shepherds from Kangra, Mandi, and Kullu can be seen with their herds of sheep at Chandra pastures. According to legend, this lake is the location from where God Indra's chariot picked up Yudhishtira, the eldest of the Pandava brothers. As a result, this lake is a revered one and draws a large number of devotees.
Lake	Pangon Tso lake in Sikkim, India
Location	100 km southeast of Leh Ladakh, Jammu and Kashmir, India; Rutog County, Tibet
Location on map	33°43'04.59"N 78°53'48.48"E
Climate	Cold arid climate
Altitude	4,218 m above mean sea level
Surface area	The lake area is about 65,000 ha. Maximum depth of water in the lake is about 100 m. Max. length 134 km (83 miles) Max. width 5 km (3.1 miles) Surface area approx. 700 km² (270 miles²) Surface elevation 4,250 m (13,940 ft)

Indian Lakes, Table 1 (Continued)

Inflow	Input to the lake is precipitation during summer as well as winter season. Due to snowfall, thawing of catchment vegetation takes place due to which there is heavy catchment erosion during summer rainfall. Since the lake is in the valley, all the sediment load comes into the lake along with the runoff. Formerly, Pangong Tso had an outlet to Shyok River, a tributary of Indus River, but it was closed off due to natural damming. Two streams feed the lake from the Indian side, forming marshes and wetlands at the edges. Strand lines above current lake level reveal a 5 m (16 ft) thick layer of mud and laminated sand, suggesting the lake has shrunk recently in geological scale.
Type of lakes	Natural high-altitude narrow brackish lake
Ecological status	• Lake gets frozen in winter. • Overturning in the lake takes place in December and January. • Lake has a protected high-altitude cold desert National Park.
Changes over the last years	Due to decreasing trend of rainfall and accelerated sedimentation, the lake is shrinking, though quantitative data on lake shrinkage are not available.
Biodiversity	The brackish water of the lake is devoid of any micro-vegetation. Guides report that there are no fish or other aquatic life in the lake, except for some small crustaceans. On the other hand, visitors see numerous ducks and gulls over and on the lake surface. There are some species of scrub and perennial herbs that grow in the marshes around the lake. The lake acts as an important breeding ground for a variety of birds including a number of migratory birds. During summer, the Bar-headed goose and Brahmini ducks are commonly seen here. The region around the lake supports a number of species of wildlife including the kiang and the marmot.
Recreation	Center of international tourism.
Commercial use	The lake is a strategic site situated in upper drainage basin of Indus river. In the first week of June every year, an annual fair takes place around this lake. This annual fair is called "Sindhu Darshan."
Studies undertaken	Limnological and biological study
Governing authority	Sikkim State Government
General	Pangong Tso is in disputed territory. The Line of Actual Control passes through the lake. A section of the lake approximately 20 km east from the Line of Actual Control is controlled by China but claimed by India. The eastern end of the lake is in Tibet and is not claimed by India. The western end of the lake is not in dispute. After the mid-nineteenth century, Pangong Tso was at the southern end of the so-called Johnson Line, an early attempt at demarcation between India and China in the Aksai Chin region. The Khurnak Fort (33°46'00"N 79°00'00"E/33.766667°N 79.000000°E/33.766667; 79.000000) lies on the northern bank of the lake, halfway of Pangong Tso. The Chinese controlled Khurnak Fort area by the end of 1952, as is the situation today. On October 20, 1962, Pangong Tso saw military action during the Sino-Indian War, successful for People's Liberation Army. Pangong Tso is still a delicate border point along the Line of Actual Control. Incursions from Chinese side are common.
Lake	Roopkund lake, Uttarakhand
Location	In Chamuli district of Uttarakhand
Location on map	30°15'43"N 79°43'55"E/30.262°N
Climate	The climate is hostile during most of the year. One gets a closer view of Trisul and other peaks higher than 5,000 m. Many waterfalls and landslides are visible on the extreme slopes of the surrounding mountains.
Altitude	About 5,029 m above mean sea level.
Type of lakes	A glacial lake in Uttarakhand state of India famous due to more than 500 skeletons found at the edge of a lake. The location is uninhabited and is located in Himalaya.
Recreation	Roopkund is a picturesque and beautiful tourist destination in the Himalayas, located near the base of two Himalayan peaks: Trisul (7,120 m) and Nandghunthi (6,310 m). A religious festival is held at the alpine meadow of Bedni Bugyal every autumn with the nearby villages participating. A larger celebration, the Nanda Devi Raj Jat, takes place once every 12 years at Roopkund. Skeleton lake is covered with ice for most of the time during the year. However, the journey to Roopkund is an enjoyable experience. All along the way, one is surrounded by mountain ranges from all sides.

Indian Lakes, Table 1 (Continued)

Studies undertaken	There are different routes for a trek to Roopkund. Generally, trekkers and adventurers travel to Lohajung or Wan by road. From there, they climb a hillock at Wan and reach Ran ki Dhar. There is some flat area where trekkers can camp for the night. If the sky is clear, one can see Bedni Bugyal and Trisul. The next camping spot is at Bedni Bugyal, which is 12–13 km from Wan. There is a huge grazing ground for mules, horses, and sheep. There are two temples and a small lake that add to the beauty of this place. One can see many Himalayan peaks from Bedni Bugyal bridge. Trekkers then go up to Bhaguwabasa, which is 10–11 km from Bedni Bugyal. From Bhaguwabasa, trekkers either go to Roopkund and come back, or they go to Shila Samundra (Ocean of Stones) via Junargalli Col Pass, which is just above the lake, and then proceed with the trek up to Homkund. The human skeletons were rediscovered in 1942 by a Nanda Devi game reserve ranger H. K. Madhwal, although there are reports about these bones from late nineteenth century. Earlier it was believed by specialists that the people died from an epidemic, landslide, or blizzard. The carbon dating from samples collected in the 1960s vaguely indicated that the people were from the twelfth century to the fifteenth century. In 2004, a team of Indian and European scientists visited the location to gain more information on the skeletons. The team uncovered vital clues including jewelry, skulls, bones, and preserved tissue of bodies. DNA tests on the bodies revealed that there were several groups of people including a group of short people (probably local porters) and a taller group who were closely related – with DNA mutations characteristic for Kokanastha Bramins in Maharashtra. Though the numbers were not ascertained, remnants belonging to more than 500 people have been found and it is believed that even more than 600 people perished. Radiocarbon dating of the bones at Oxford University Radiocarbon Accelerator Unit determined the time period to be AD 850 $\pm$ 30 years. After studying fractures in the skulls, the scientists in Hyderabad, Pune, and London determined that the people died not of disease, but of a sudden hailstorm. The hailstones were as large as cricket balls, and with no shelter in the open Himalayas, all of them perished. Furthermore, with the rarefied air and icy conditions, many bodies were well preserved. With landslides in the area, some of the bodies made their way into the lake. What is not determined was where the group was headed to. There is no historical evidence of any trade routes to Tibet in the area but Roopkund is located on an important pilgrimage route of Nanda Devi cult with Nanda Devi Raj Jat festivities taking place approximately once in 12 years.
Lake Location Location on map Climate Altitude Surface area Inflow Type of lakes Changes over the last years	Harike lake in Punjab Harike or Hari-ke-Pattan, as it is popularly called, is the nearest town to the wetland. Makhu (Ferozepur) is the nearest railway station, and the bus stand is situated 10 km south of the Harike town, which connects to Ferozepur, Faridkot, and Bhatinda by the National Highway. The headworks built on the Sutlej River downstream of its confluence with Beas River and the reservoir created, which form the Harike lake and the enlarged wetland, is a purposeful project, which acts as the Headworks for irrigation and drinking water supplies, through the Ferozepur, Rajasthan, and Makku feeder canals with total carrying capacity of 29,000 ft³/s (820 m³/s), to supply to the command areas located in the states of Punjab and Rajasthan. The grand Indira Gandhi Canal in Rajasthan is fed from this source. The lake is triangular in shape, with its apex in the west, bounded by a bund called the Dhussi Bund forming one side, a canal in the second, and a major road on the third. The periphery of the lake is surrounded by agricultural land and the wetland is reported to be rich in groundwater resources. 31°10'N 75°12'E 31.17°N Monsoon climate dominates the catchment draining into the wetland. 210 m above mean sea level 4,100 ha. Average depth is few centimeters whereas maximum depth is around 200 cm. Beas and Sutlej Rivers Freshwater The wetland which is in existence since 1953 underwent changes over the years due to several factors, some of which are the following: • Encroachments on the wetland habitat for intensive agriculture with resultant effluents of agricultural chemicals and also controversial encroachments. • Utilization of surface and groundwaters for irrigation • Effluent discharge of untreated waste from towns and villages from industrial, urban, and agricultural activities into the rivers which feed the wetland resulting in extensive weed growth (Water Hyacinth) in the wetland (polluted water discharged was reported to be about 700 million liters per day (mld)) • The profuse growth of water hyacinth had covered 80% of the open water surface resulting in the 33 islands getting enclosed.

Indian Lakes, Table 1 (Continued)

Biodiversity

- Soil erosion and siltation due to deforestation of the fragile lower Shivalik hills which form the catchment of the wetland.
- Illegal fishing and poaching in spite of the Wildlife (Protection) Act.
- Indiscriminate grazing in the catchments resulting in damage to the wetland ecology.
- A remote sensing study of the Wetland area coupled with the analysis of rainfall, discharge, and groundwater level showed that the flow pattern had diminished and the size of wetland area had reduced by about 30%, over a 13 years study period ([Indian Meteorological Department's Atlas for maximum possible sunshine duration](#)).
- The ecological crisis had reached such a stage that environmentalists estimated lifespan of the wetland to be decreasing.

Harike Wetland also known as "Hari-ke-Pattan," with the Harike lake in the deeper part of it, is the largest wetland in northern India in the Ferozepur district of the Punjab state in India. The wetland and the lake were formed by constructing the head works across the Sutlej river, in 1953. The headworks is located downstream of the confluence of the Beas and Sutlej rivers. The rich biodiversity of the wetland which plays a vital role in maintaining the precious hydrological balance in the catchment with its vast concentration of migratory fauna of waterfowls including a number of globally threatened species (stated to be next only to the Keoladeo National Park near Bharatpur) has been responsible for the recognition accorded to this wetland in 1990, by the Ramsar Convention, as one of the Ramasar sites in India, for conservation, development, and preservation of the ecosystem.

The rich biodiversity of the wetland, with several species of birds, species of turtles, species of snakes, taxa of amphibians, taxa of fishes, and taxa of invertebrates, is reportedly unique.

The wetland was declared a bird sanctuary in 1982 and named as Harike Pattan Bird Sanctuary with an extended area of 8,600 ha (Geological Survey of India & Report, 1988). Bombay Natural History Society (BNHS) carried out research and a bird ringing program during the period 1980–1985 (Cavazza, 1993). An Ornithological field laboratory was proposed to be established by BNHS.

Two hundred species of birds visit the wetland during winter season of which some of the well-known species are the (1) Cotton Pygmy Goose (genus *Nettapus*), (2) Tufted Duck (*Aythya fuligula*), (3) Yellow-crowned Woodpecker (*Dendrocopos maharattensis*), (4) Yellow-eyed Pigeon or Pale-backed Pigeon, (5) Water Cock (*Gallicrex cinerea*), (6) Pallas's Gull or Great Black-headed Gull (*Ichthyiaetus ichthyiaetus*), (7) Brown-headed Gull (*Chroicocephalus brunnicephalus*), (8) Black-headed Gull (*Chroicocephalus ridibundus*), (9) Yellow-footed Gull (*Larus michahellis*), (10) Indian Skimmer (*Rynchops albicollis*), (11) White-winged Tern (*Chlidonias leucopterus*), (12) White-romped Vulture, (13) Hen Harrier (*Circus cyaneus*), (14) Eurasian Tree Sparrow (*Passer montanus*), (15) Hawk (subfamily Accipitrinae), (16) Eurasian Hobby (*Falco subbuteo*), (17) Horned Grebe (*Podiceps auritus*), (18) Black-necked Grebe (*Podiceps nigricollis*), (19) Great Crested Grebe (*Podiceps cristatus*), (20) White-browed Fantail (*Rhipidura aureola*), (21) Brown Shrike (*Lanius cristatus*), (22) Common Woodshrike (*Tephrodornis pondicerianus*), (23) White-tailed Stonechat (*Saxicola leucurus*), (24) White-crowned Penduline-tit (*Remiz coronatus*), (25) Rufous-vented Prinia (*Prinia burnesii*), (26) Striated Grassbird (*Megalurus palustris*), (27) Cetti's Warbler (*Cettia cetti*), (28) Sulphur-bellied Warbler (*Phylloscopus griseolus*) and (29) Diving duck (pochards).

The wetland's rich floating vegetation comprises the following:

- *Eichhornia crassipes* dominates in 50% area.
- *Azolla* sp. is sparsely seen in open water areas.
- *Nelumbo nucifera*, the Lotus, the prominent rooted floating vegetation.
- *Ipomoea aquatica*, at the lake periphery in the shallower region.
- *Najas*, *Hydrilla*, *Ceratophyllum*, *Potamogeton*, *Vallisneria* (eelgrass, tape grass vallis) and Charales are the species of submerged vegetation.
- *Typha* sp. is the dominant emergent marsh vegetation.
- Tiny floating islets are formed by *Eichhornia crassipes* and other grass species in the mud and root zone all over the wetland.

Dalbergia sissoo, *Acacia nilotica*, *Zizyphus* sp, *Ficus* sp, alien *Prosopis juliflora* in large clumps and other trees are planted along the embankment. The State Wildlife Department has constructed earthen mounds in the marsh area with trees planted on it to increase nesting sites for the birds.

Studies undertaken

This man-made, riverine, lacustrine wetland spreads into the three districts of Amritsar, Ferozepur, and Kapurthala in Punjab and covers an area of 4,100 ha. Conservation of this wetland has been given due importance, since 1987–1988, both by the Ministry of Environment and Forests, Government of India and the Punjab State Government (through its several agencies), and over the years several studies and management programs have been implemented.

The Punjab State Council for Science & Technology has reported that the water quality of the lake is mostly of "A" Class as per the designated best use criteria even though large volumes of polluted water discharge into the wetland from industries and urban centers.

Indian Lakes, Table 1 (Continued)

Governing authority	The gravity of the degraded status of the wetland has been addressed for implementing several restoration measures by a plethora of organizations/agencies/research institutions of the central and state governments and also the Indian Army Units located in the area. The measures undertaken to conserve the wetland have covered the following actions. The Chief Minister of the State of Punjab instituted, in 1998, the Harike Wetland Conservation Mission to: - Prepare a Master Plan for the integrated conservation and development of the Harike wetland - Undertake specific projects and programs for the conservation of the ecosystem of the Harike region - Regulate, screen, and monitor all development activities which have a bearing on the Harike wetland ecosystem - Evaluate all plans and proposals of all departments of the Government which concern the future of Harike The menace of water hyacinth was addressed by the Indian Army (Western Command, Vajra Corps.) in the year 2000, in a joint effort initiated by the Chief Minister of the State. Under the Pilot Project named "Sahyog" the Army adopted several innovative mechanical system of weed removal. The Army General reporting on the progress of the works stated: Through a number of innovative methods, we succeeded in making dynamic booms, winches, etc. After the operation, we have placed static and dynamic booms at strategic points in the Harike lake to hold back the floating mats of water hyacinth so that it does not spread. At the end of 6 months of untiring labor by our team, we had opened four channels, which had got choked with silt over the years. We also planted 750 saplings of plants of 2 years of age on the island for birds to nest and roost in future. - The Punjab State Council for Science and Technology evolved a management plan which involved (Dooge, 1975): - Opening of sluice gates during monsoon - Monitoring of water quality migration period - Fencing some of the selected portions from encroachment - Afforestation of the catchment area - Survey, mapping, and notification - Soil conservation - Education and Public awareness
Lake	Kanjli Wetland, Punjab
Location	Kanjli wetland which subsumes the Kanjli lake is located in the Kapurthala district of Punjab state in India and was created in 1870 by constructing the headworks across the perennial Bien River, a tributary of the Beas River to provide irrigation facilities to the hinterland. The Kanjli ecological Wetland region around the village Kanjli is 4 km (2.5 miles) from the Kapurthala town, also the district headquarters, and is thus well connected by road network to all parts of the state and rest of the country.
Inflow	The Kali Bein River, originating near village Dhanoa, upstream of Budho Bark Regulator in Hoshiarpur District, formerly a main tributary of the Beas River feeds the Wetland and the lake. The Bein has now become an independent river due to siltation and westward swing of the Beas River. Agricultural development dominates the catchment of the wetland. The Bein River has contributed to the formation of fertile plains by bringing down large sediment loads during floods. Depth of water in the lake has a seasonal variation of 3.05 m (10 ft) to 7.62 m (25 ft) depending on the season and inflow discharge. Catchment area is mainly under agriculture. The wetland is in the semi-arid zone and receives an average annual rainfall of about 620 mm. The temperature varies from a maximum of 45°C in summer to an average of 60°C during winter with occasionally freezing temperatures. The Kali Bein and its wetland provide water supply for agriculture in the Kapurthala district, recharges the groundwater, drains excessive rainwater from sensitive crops like wheat, potato, etc., and acts as a sponge by absorbing the floodwaters.

Indian Lakes, Table 1 (Continued)

Type of lakes	A man-made wetland
Ecological status	The Kanjli Wetland is one of the man-made wetlands in India identified by the Government of India, as per the Expert Group's (set up in 1983 by the Ministry of Environment and Forests) report published in 1990. The Expert Group has based its directory on the basis of the definition enunciated by the Ramsar International Convention on Wetlands: “Areas of marsh, fen, peatland, or water whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish or salt, including areas of marine water, the depth of which at low tide does not exceed six meters.” Further, considering the definition of wetlands given by Cowden in 1979 for classification of wetlands in USA, three key attributes of hydrology (the degree of flooding or soil saturation), wetland vegetation (hydrophytes), and hydric soils have also been considered for identification. In this list, Mangroves are not included since it falls under a separate category. The Expert Group's directory has made a distinction between Natural and Man-Made wetlands (including wetlands of less than 100 ha area). In India, in its 24 states and two union territories (as per the 1990 report), there are 2167 number of natural wetlands with a total area of 1.45 million hectares and Man-Made wetlands of 65,254 number with total area of 2.59 million hectares. The inland water bodies listed in the report cover lakes, tanks, reservoirs, etc.
Changes over the last years	In the Wetland, the ecological status of the Kanjli lake, in particular, has been threatened on account of the following issues: • Extensive growth of water hyacinth due nutrients and pesticides from adjoining agricultural fields • Anthropogenic pressure and consequent land encroachment • Eutrophication, particularly due to in situ decay of hyacinth • Conversion of wetland for agriculture, human habitation, industrial expansion, and recreational activities • Illegal and indiscriminate fishing causing disturbance to bird life
Biodiversity	The rich biodiversity of the wetland comprising aquatic, mesophytic, and terrestrial flora and fauna, including some important species of plants and animals, was recognized internationally by the Ramsar Convention in 2002 by designating the Kanjli lake in the List of Wetlands of International Importance. In this context, it is reported that in Punjab State, which has 14 wetlands covering an area of 225.76 km² (Two per cent of the geographical area of the State), three of its wetlands, namely the Kanjli Wetland (covering an area of 490 ha of which the Kanjli lake water spread is 184 ha), the Harike Wetland (4,100 ha), and the Ropar Wetland (1,365 ha) have been chosen by the Ministry of Environment and Forest (MoE&F), Government of India, for their conservation and management and are now also included in the Ramsar list covering a total area of 5,650 ha. Kanjli is upstream of Harike Wetland located in the Beas river basin, while the Ropar Wetland is in the Roopnagar district. The flora and fauna recorded in the Wetland and the Kanjli lake within it (some of them are pictured in the gallery) are the following: • Twelve varieties of trees recorded in the wetland are (1) <i>Acacia arabica</i>, (2) <i>Albizia lebbek</i>, (3) <i>Azadirachta indica</i>, (4) <i>Dalbergia sissoo</i>, (5) <i>Eucalyptus hybrid</i>, (6) <i>Ficus bengalensis</i>, (7) <i>Mangifera indica</i>, (8) <i>Melia azedarach</i>, (9) <i>Morus alba</i>, (10) <i>Prosopis juliflora</i>, (11) <i>Syzygium cumini</i> and (12) <i>Ziziphus mauritiana</i> • Shrubs recorded are <i>Calotropis procera</i>, <i>Ipomoea crassicaulis</i>, and <i>Tamarix dioca</i> • Herbs noted are <i>Saccharum munja</i>, <i>S. spontaneum</i>, <i>Scirpus</i> sp., and other common herbs. 11 species of aquaflora, 34 species of zooplankton, and 15 species of macroinvertebrate species have been reported. <i>Aqua fauna</i> According to the District Gazetteer and the study done by the National Environmental Engineering Research Institute (NEERI), 17 fish species (in Bein river and the lake) have been reported which includes the common fish species of <i>Catla catla</i>, <i>Channa marulius</i> (Great snakehead), <i>Cyathus striatus</i>, <i>Cirrhinus mrigala</i>, <i>Labeo calbasu</i>, and <i>L. rohita</i>. The tortoise is the common reptile reported in the area. Birds found in the wetland are of two varieties, viz., common resident birds (28 species) and the migratory birds of nine species. The migratory birds are: (1) Various species of goose, (2) White eyed pochard, (3) Wigeon, (4) Tufted pochard, (5) Common Teal, (6) Large whistling teal, (7) Pintail, (8) Mallard and (9) Shoveller <i>Fauna</i> The mammalian fauna seen in the wetland are (1) the Indian civet, (2) mongoose, (3) Indian porcupine, (4) squirrel, and (5) common Indian hare.

Indian Lakes, Table 1 (Continued)

Studies undertaken	The water and sludge quality of the wetland has been studied by the Punjab Pollution Control Board. Their report indicates that quality generally conforms to Class “B” with some degree of quality degradation to Class “D” sometimes during December. From a satellite imagery study of the wetland it has been inferred that Kanjli lake could be categorized under low turbidity class (dark blue hue) during pre-monsoon period and moderate turbidity class (medium blue) during post-monsoon season which is indicative of regimentation occurring in the lake during post-monsoon season.
Governing authority	The erstwhile Maharaja of Kapurthala (Raja Randhir Singh – 1862–1870) built the headworks on the river Kali Bein that resulted in the creation of the Kanjli Wetland which subsumes the sparkling lake by the same name. The Maharaja also built a retreat, in the French architectural style, in the forest set in lovely natural scenery, on the banks of the lake, which was named “The Villa” or the “Villa Buona Vista.” His royal successors live in this retreat even now. The lake has been developed as a tourist destination with facilities for fishing and boating. A traditional Mela or exhibition is held here during Deepavali festival.
General	Conservation measures The conservation and management measures undertaken with assistance provided by the Ministry of Environment & Forests, Government of India (MoEF, GOI) by the Environment Division of the Punjab State Council for Science & Technology under the Directive of the State Level Steering Committee are the following (Indian Meteorological Department's Atlas for maximum possible sunshine duration): • Detailed mapping of the wetland for declaring and notifying the Kanjli Wetland as protected area under the Environment Protection Act, 1986. • Judicious Hyacinth (weed) control by the Irrigation department, District Police, and even the Army Units, by manual methods. Conveyor belt system as a Mechanical method to clear the weeds is also being tried. • Hyacinth control through biological control by releasing two weevil species (which have proved been found effective world wide and introduced in the downstream in the Harike Wetland Ecosystem) of <i>Neochetina bruchi</i> and <i>N. eichorniae</i>. Release of moth <i>Sameodes albiguittal</i> is also being considered as an option. • Introduction of more fish species in the lake judiciously to avoid any adverse effects of exotic species. • Afforestation measures around the lake area and in the small islands, with mixed indigenous species of trees to prevent soil erosion resulting in siltation reduction in the lake, to attract large species of birds to nest and roost and to enhance the ecosystem. • Selective fencing of the wetland to prevent excessive grazing to preservation of important pockets provide habitat for wading birds and to check encroachments. • Monitoring of water quality continuously to check the degree of external nutrient loading of the lake waters and to evolve appropriate preventive and curative steps. • Public awareness campaigns through mass media, educational material, camps, etc., of the wetland ecosystem with the help of Voluntary Organizations. • Continued scientific research on Biological and hydrological components, and Productivity potential with respect to economic value, social aspects of heritage and to rate the significance of the wetland.
Lake	Ropar Wetland, Punjab
Location	Ropar Wetland, also named Ropar lake is located close to the Rupnagar city, 45 km northwest of Chandigarh City, in Roopnagar and Nawanshahr districts of Punjab. Chandigarh is the nearest airport, which connects to the rest of India.
Location on map	31°01'N 76°30'E 31.02°N 76.50°E
Climate	Climatically, the drainage area of the wetland falls under semi-arid zone of Punjab with mean annual rainfall of 1,518 mm. Initially, in the year 1882, a small headwork was constructed on the right bank of Sutlej River, near Ropar town, to supply water to Sirhind Canal. Subsequently, in 1952, a head regulator was constructed to divert water not only to the Bist Doab Canal but also to Sirhind Canal and to the Bhakra Main Canal (upstream of the wetland), for irrigation, industrial, and domestic use.
Altitude	275 m above mean sea level.
Surface area	The total area covered by the wetland is 1,365 ha, which includes 800 ha area of the river and the reservoir, 30 ha of forest area named as “Sadavarat Forest,” and 30 ha under marshy plants. Average depth is 0.5 m, where as maximum depth is 6 m. The wetland is surrounded by hills in the northwest and by plain area in the south and southeast.

Indian Lakes, Table 1 (Continued)

Inflow	Sutlej River
Type of lakes	A man-made freshwater riverine and lacustrine wetland.
Ecological status	This important ecological zone is located in the Shivalik foothills of the Lower Himalayas and was created in 1952 on the Sutlej River, in the Punjab state of India, by building a head regulator to store and divert water for beneficial uses of irrigation, drinking, and industrial water supply. <i>Flora and fauna</i> The wetland is rich in flora and fauna which are categorized below. <i>Flora</i> A total of 19 species of trees and 14 species of bushes and grasses are recorded. Of these, the tree species are (1) <i>Acacia catechu</i>, (2) <i>Ameles modesta</i>, (3) <i>Acacia nilotica</i>, (4) <i>Albizia lebbek</i>, (5) <i>Azadirachta indica</i>, (6) <i>Bombax ceiba</i>, (7) <i>Cassia fistula</i>, (8) <i>Dalbergia sissoo</i>, (9) <i>Eucalyptus tereticornis</i>, (10) <i>Ficus benghalensis</i>, (11) <i>Ficus religiosa</i>, (12) <i>Mangifera indica</i>, (13) <i>Melia azedarach</i>, (14) <i>Moringa oleifera</i>, (15) <i>Morus indica</i>, (16) <i>Prosopis juliflora</i>, (17) <i>Salix willow</i>, (18) <i>Syzygium cumini</i> (Jambul), and (19) <i>Zizyphus jujuba</i>. <i>Aqua fauna</i> Wetland is a major source of fisheries since large species of fishes have been recorded; some of the commercially important ones are: • Rohu; <i>Labeo gonius</i> Seerha; <i>Labeo calbasu</i> Kalbans or Dhari; <i>Labeo dero</i> Gid; <i>Labeo dyocheilus</i> (Kunni); <i>Catla catla</i> Thal; <i>Cirrhinus mrigala</i> Mori; <i>Puntius sarana</i> Puthi; <i>Cyprinus carpio communis</i> (Common Carp); <i>Cyprinus carpio spicularis</i> (Mirror carp); <i>Ceenopharyngodon idelle</i> (Grass Carp); <i>Wallago attu</i> Mali; <i>Aorichthys seenghala</i> Sangarha; <i>Mastacembelus armatus</i> Sam (Tire track eel); <i>Ambassis ranga</i> Shisha Mach; <i>Channa punctatus</i> Dolla (Snake-headed fish); and <i>Channa striata</i> Curd. • Four species of Amphibia (Frogs) have been noted. <i>Avi fauna</i> Several species of birds have been recorded which include 49 species of local birds, 11 species of migratory birds, 3 species of rare birds, and 54 species of common birds. Some of the rare birds among the migratory birds noted are: <i>Dinopium benghalense</i>; Golden-backed Woodpecker; <i>Megalaima haemacephala</i>; Crimson-breasted barbet; and <i>M. zeylanica</i> Green barbet <i>Fauna</i> Two species of tortoise, viz., <i>Geoclemys hamiltonii</i> and <i>Chitra indica</i> (endangered species), five species of lizards, 11 species of snakes including the threatened species of <i>Python molurus</i> or Indian python or ajar are found in the wetland. <i>Food chain</i> The food chain in the wetland is basically well balanced as it has both deepwater and shallow water characteristics, and the ecosystem is stated to be almost self-sufficient and self-regulating.
Changes over the last years	Over the years several adverse impacts on the quality of the wetland have been reported. Some of the important ones which invited remedial actions are: • Acute problems of siltation from the adjoining barren and fragile hills. Bare hills of the catchment are subject to continuous erosion leading to shrinkage of wetland area. • Unwarranted interference with the resident and migratory birds. • Unauthorized fishing and poaching of wildlife causing damage to species. • Increase in effluents from industrialization in the upstream area of the wetland, such as the Fertilizer plant at Nangal and Thermal Power Plant at Ropar. • Effluents of chemical pollutants like agrochemical residues runoff, industrial effluents, and sewage from some towns in the upper reaches of the wetland. • Growth of invasive weeds.
Biodiversity	The area has at least 9 mammal, 154 bird (migratory and local), 35 fish, 9 arthropod, 11 rotifer, 9 crustacean, and 10 protozoan species, making it biologically diverse. The endangered turtle <i>Chitra indica</i> and the threatened snake <i>Python molurus</i> (at lower risk) are reported to be residents in the wetland. Considering the wetland's diverse and rich biodiversity, Ramsar Convention has included Ropar Wetland (listed as Ropar lake) as one of the Ramsar sites among the 21 sites listed under India, for "the conservation of global biological diversity and for sustaining human life through the ecological and hydrological functions they perform."
Recreation	The wetland is a popular tourist attraction for bird watching and boating. A tourism complex called the "Pincasia" is located within the wetland boundary, which is run by the Punjab Tourism Development Corporation. A Boat Club is also functioning.
Commercial use	Agricultural crops such as wheat, rice, sugarcane, sorghum, etc., are grown in the farmlands in the area surrounding the wetland but the hills have thin vegetation and are exposed to intensive grazing.

Indian Lakes, Table 1 (Continued)

Studies undertaken	Water Quality that determines the health of ecosystem of the wetland was monitored by the Punjab Pollution Control Board (PPCB) in the year 1998–1999. The water quality was reported to be of “A” category as the river entered into Punjab and deteriorated to “D” category downstream of Ropar lake, mainly due to the industrial effluents from a number of factories and industrial units. Further studies on physico-chemical analysis of important parameters, biological estimations as well as pesticide residue analysis have been initiated. A scientific study of the food chain has brought out the following sequence of facts: • Sunlight, pH, inorganic salts, nutrients, and dissolved gases are the main abiotic components of the wetland ecosystems with the organic matter caused by the death and decay of animals and plants accumulating at the bottom of the lake. • Decomposition at the bottom of the lake takes place due to a variety of heterotrophic microbes such as bacteria, actinomycetes, and fungi; <i>Aspergillus</i> sp., <i>Rhizopus</i> sp., <i>Curvularia</i> sp., <i>Paecilomyces</i> sp., <i>Saprolegnia</i> sp., etc., are main species causing the decomposition. • The producers of organic matter are the eutrophic green plants and some photosynthetic bacteria; the rooted submerged, floating, and emergent hydrophytes being the <i>Typha</i> sp., <i>Eleocharis</i> sp., <i>Sagittaria</i> sp., <i>Nymphaea</i> sp., <i>Potamogeton</i> sp., <i>Vallisneria</i> sp., <i>Eichhornia</i> sp., <i>Lemna</i> sp., etc., and minute, floating, or suspended lower plants like filamentous algae, diatoms, chlorococcales and flagellates. • Herbivores such as the mollusks, crustaceans, rotifers, and some insects are the primary consumers which feed directly on plants. • Plant remains and organic matter nourish detritivores like the Chironomidae sp., mollusks, mites, some crustaceans, and small fishes. • Marginal rooted macrophytes are consumed by mammals such as buffaloes, cows, etc., which frequent the shores of the lake. • Hydrophytes are also the food source of some birds. • Carnivores like the Predator beetles and bugs, dragonflies are the secondary consumers which feed on insects, mollusks, rotifers, and crustaceans. Carnivorous fishes also belong to this category. • Large carnivorous fishes and birds are the tertiary consumers which feed on small fishes and insects. • Top most consumer level is that of the human being and the fish eating birds, which feed mainly on fishes.
Governing authority	<i>Restoration measures</i> The Punjab State Council for Science & Technology has evolved several conservation programs with support from the Ministry of Environment and Forests (MoE&F) of the Government of India. Some of the programs implemented include mass awareness campaigns and promotion of public participation in the wetland conservation. A few of the measures planned and under various stages of implementation are: • Afforestation and soil conservation in the highly erosion-prone catchment areas of the wetland. • To erect chain-link fencing of strategic areas of the wetland to prevent exploitation of vital wetland resources and prevent encroachments of the wetland. • Detailed survey, including remote sensing survey and preparation of comprehensive maps. • Detailed taxonomic studies of plant and animal species. • Introduce fish species sustain fragile relationship between the Fish level and the other biotic resources like birds and primary producers and to set up new fish seed farms in addition to refurbish the existing ponds. • Economic assessment.
General	An archaeological museum of the Archaeological Survey of India at Ropar has displays of the antiquities unearthed during the excavations of mound in the area along with photographs displaying excavation material. The Museum depicts a sequence of six cultural periods or phases, with some breaks from Harappan times to the present day, found in the 21 m high ancient mound known as Nalagarh Tibbi overlaying the Shiwalik (also spelt Sivalik) deposition on the left bank of the Satluj River where it emerges into the plains. A deep well with a stone inscription of Emperor Shah Jahan (AD 1627–1658) has been located at the foot of the mound. The excavations have established that advanced civilization similar to the Harappa and Mohenjodaro Civilization prospered in Ropar town, an integral part of the wetland. The wetland area has also a modern history in respect of Anglo–Sikh relations. On 26 October 1831, sitting under the shade of an old ficus tree on the bank of Sutlej River, Maharaja Ranjit Singh and Lord William Bentinck, the British Governor General, signed an agreement defining the Anglo–Sikh relations and territories.
Lake	Sultanpur Jheels in Haryana
Location	Located at 15 km west of Gurgaon.
Location on map	28°28' N and 76° 55' E

Indian Lakes, Table 1 (Continued)

Climate	The climate of the region is monsoon climate with very scanty rainfall.
Altitude	220–230 m above mean sea level
Surface area	Having total area of 13,727 ha.
Inflow	Local inflow during monsoon rainfall.
Outflow	The lakes flood during monsoon and heavy rainfall
Type of lakes	These are a group of shallow freshwater lakes
Changes over the last years	The siltation in the lakes is on the increasing scale. There is an excavation of sand from bed of the lake for lime industry. Planting of the salt-tolerant species in surrounding area and restoration is proposed to reduce erosion.
Biodiversity	It was declared as Bird Sanctuary in 1971.
Studies undertaken	Waterfowl census had been carried out and Avi fauna has been well documented.
Lake	Surajkund, Haryana
Location	Surajkund village, Faridabad district, Haryana. Surajkund is an ancient reservoir of the tenth century, 2 km away to the southwest from a more ancient dam of the eighth century called the Anagpur Dam; both are located in Haryana, India.
Location on map	28°29'01"N 77°18'57"E to 28.48361°N 77.31583°E
Surface area	40 ha
Inflow	The lake's drainage basin is part of the Aravalli hill ranges. It is fed from the northwestern side by a local nallah (stream) that initially feeds the Anagpur dam on the upstream.
Type of lakes	Surajkund (literal meaning is "Lake of the Sun") is an artificial Kund ("Kund" means "lake" or reservoir) built in the backdrop of the Aravalli hills with an amphitheater-shaped embankment constructed in semicircular form.
Changes over the last years	The storage in the tank or lake has been seriously affected since the catchment area contributing flows into the Surajkund (lake) from villages such as Anangpur, Lakkarpur, Ankhir, and Meola Maharajpur has been used for extensive mining and for large habitations, which has disturbed the drainage system and thus obstructed the gravity flow of rainwater from the basin into the reservoir. This situation is stated to have also affected the flora and fauna of the area.
Recreation	In the backdrop of the lake, during the spring season, every year from February 1–15, a colorful traditional craft festival of India is held in the precincts of Surajkund. This fair was first started in 1987. Traditional craftsman (artists, painters, weavers, and sculptors) from all parts of the country participate in this annual celebration named as the "Surajkund Crafts Mela" or "Surajkund designer's Village." Designer items created by 50 best designers and craftsmen in wood, metal, bamboo, iron, glass, textiles, and stone can be seen here. This Mela (fair) is visited by lovers of arts and crafts from all over the world. The fair is held with a different theme every year on Indian culture and crafts. The theme, specific to a state of India, is depicted at the entrance to the Mela grounds and provides an ambience of that particular state with characteristic colors, materials, architecture, furniture, and decorations. The crafts on display in the stalls (400) is of particular crafts of that state. The Mela also includes a food festival covering some of the popular cuisines from different parts of the country. Entertainment in the form of famous rhythms and dance of folk theater are also held here during the festival. During 2009, with Madhya Pradesh as the theme state, 50 crafts persons from SAARC countries, Thailand, and Egypt also participated in the Mela. The show was titled "Hemvati-Khajuraho" as a part of the 23rd annual Surajkund Crafts Fair event. Sanchi Stupa (a world heritage site in Madhya Pradesh) formed the backdrop for the festival. Surajkund, also called the Peacock lake, because of its delightful beauty is now a well-known tourism destination in Haryana state. Activities of water sports such as Kayaking are also an attraction at this lake. It is 8 km (5 miles) by road from South Delhi and 20 km (12 miles) from the heart of the New Delhi city. It is well connected to all parts of the city. The nearest airport is the Indira Gandhi International Airport, 25 km (16 miles) away. The nearest railway stations are the New Delhi Railway Station and the Nizamuddin Railway Station, 22 km (14 miles) and 21 km (13 miles) respectively by road. It is also approached by road and rail from Faridabad (headquarters of the district) and Gurgaon cities. It is 11.5 km (7 miles) from the Qutub Minar and 3 km (2 miles) Tughlaqabad, two historical places in Delhi.

Indian Lakes, Table 1 (Continued)

Studies undertaken	From a study of the prehistoric findings along the ridges of Surajkund reservoir, Anagpur Dam, and around Delhi and adjoining parts of Haryana, it has been inferred that the southern hilly area of Delhi and Haryana was environmentally suited for pre-historic man to settle here. In the Aravalli hill ranges, which spread over Delhi and Haryana, where the Surajkund and the Anagpur Dam are located, ancient Stone Age relics have been revealed. The Aravallis which strike out in two directions from Delhi exhibits a topography of low and rugged hills. The stratigraphy in the area is considered to consist of reddish rocks and scrub and has the luxuriance of the Stone Age progression. Stone Age materials have been unearthed in the region at 43 sites on the road from Delhi to Surajkund and south of the Surajkund-Faridabad road, Anangpur hills and Ankhir pahari on the road on the low ridge from Faridabad to Surajkund. The Stone Age relics comprise Microliths and lower Paleolithics (Indian Meteorological Department's Atlas for maximum possible sunshine duration).
General	It is said to have been built by the Tomar king Suraj Pal of Tomar dynasty in the tenth century. Tomar was a sun worshipper and he had therefore built a Sun temple on its western bank. Another "kund" by the same name as "Suraj Kund" existed in Sunam city, a tahsil and subdivision of the Sangrur District in Punjab. This was devastated by Mahmood Ghaznavi. The temple is now in ruins. According to bardic tradition (a tradition steeped in the history and traditions of clan and country), the Tomar kings who initially lived near the Aravalli hills shifted to the Surajkund area near Lal Kot, which was built by the Tomars. Lal Kot was renamed as Qila Rai Pithora, after Prithvi Raj Chauhan (the second last Hindu king of Delhi). Archaeological excavations have revealed existence of a Sun temple here based on ruins that can be seen even now. Certain carved stones were recently recovered from the reservoir. Some stones have also been reused in subsequent restoration works. Some historians also claim that it was named after King Suraj Pal himself who built it. It is also said that Suraj Pal built this lake for his daughter. During the Tughlaq Dynasty rule of Feroz Shah Tughlaq (1351–1388), the reservoir was refurbished by rebuilding the steps and terraces with stones in lime mortar. On the western bank of the reservoir, a garhi (cave-like structure) was built close to the ancient site of the Sun temple. Though historians have not specifically alluded to this tank, it is also said that it was built in AD 686 by Suraj Pal (after whom the tank is probably named), son of Anang Pal I. It is in the form of a segment (semicircular) with the chord on its west side. Another theory for the name "Suraj" suffixed to the kund (lake) is that it was named after the Sun Temple that existed on the east side of the lake. Even though the Tomar dynasty vanished in the twelfth century, the Surajkund has not been affected. It attracted the attention of the Haryana Government to develop the area as a tourist spot by introducing an annual crafts "Mela" or "fair" titled "Surajkund Crafts Mela" in the precincts of the lake, which over the years has attracted wide publicity and become an iconic event.
Lakes of Western India	
Lake	Pichola lake in Rajasthan
Location	5 km from Udaipur City Railway
Location on map	19°43'N 85°19'E/19.717°N
Climate	Arid climate. Average annual rainfall is 700 mm
Altitude	587 m above mean sea level
Surface area	Presently, area of the lake is about 3.0 km ² , maximum depth of water is about 4.0 m, and minimum depth is about 1.0 m. The lake used to be of 10.5 km ² in area, 8.0 m in maximum depth, and 5.0 m in minimum depth even up to the beginning of twentieth century.
Inflow	Runoff from the catchment area of about 150 km ² of hilly tract.
Outflow	Pichola lake is connected to other lakes in Udaipur City such as Fathesagar lake, Dudh Talai, and Udaisagar lake. Spillway from Pichola goes to Fathesagar, Spillway from Fathesagar goes to Udaisagar through Ayar river, and spillway from Udaisagar goes to river Bechar.
Type of lakes	Pichola lake is a man-made freshwater lake.
Ecological status	Due to rapid deforestation activities in the Aravalies (in catchment area of the lake) sediment load in the lake is increasing year by year. The lake thus created has been filled by sediment deposits to its present level. Non-point source of pollution due to heavy tourist flow to the lake. Pollution mostly includes wastes left by tourists, domestic sewage, etc., into the lake throughout the year.
Changes over the last years	Hydrology of the lake and its catchment has changed over years. The unorganized mining of soil from the lake bed is helping in increasing the capacity of the lake.
Biodiversity	Different types of migratory birds visit the lake during different seasons of the year.

Indian Lakes, Table 1 (Continued)

Recreation	Lake Palace inside the lake and City Palace on the hillock by the side of the lake are famous spots of tourist attraction. These two palaces are the architectural feat of their own time. People from all over the world visit Udaipur City and Pichola lake to see the majestic lake and enjoy boating as well as fishing in the lake.
Commercial use	The lake houses Hotel lake Palace. The commercial value of lake is related to the commercial value of the Hotel. The economy of city of Udaipur is totally dependent on the amount of water in the lake, as tourists get drawn to the lake when the lake is full.
Studies undertaken	Limnological studies by Sukhadia Univeristy at Udaipur. National Institute of Hydrology, Roorkee, India has taken studies for detailed hydrological investigations of Pichola lake and development of model for hydrological processes for the lake and its catchment.
Governing authority	Rajasthan State Government Maharana of Mewar Memorial Foundation
General	Pichola lake was constructed during the period of 1382–1411. Present status of Pichola Lake is such that the lake has completely dried up. Lake Palace Authority just maintains a channel for ferrying to Lake Palace.
Lake	Jaismond lake in Rajasthan
Location	Situated in the valley of Aravalies, 51 km from Udaipur.
Location on map	
Climate	Semiarid climate, annual average rainfall in the catchment is 800 mm.
Altitude	720 m above mean sea level.
Surface area	Presently lake area is about 30 km², maximum depth of water in the lake is about 20 m, and the lake perimeter is about 24 km. The lake used to be 63 km² in area, 33 m in maximum depth, 30 m in minimum depth, and 44 km in lake perimeter in the beginning. Out of total lake area of about 63 km², there are different islands covering an area of about 15 km².
Inflow	From the catchment area
Outflow	No outflow. Loss of water is only through evaporation.
Type of lakes	Jaismond lake is one of the largest man-made freshwater lake in the world, constructed 420 years ago in A.D. 1685.
Ecological status	- Still the lake water is fresh and sweet in taste. - Profusion of aquatic vegetation and fish resources. - There is a National WildLife Park on the side of the lake. In this WildLife Park, wild animals roam about freely in their natural way.
Changes over the last years	The earthen dam was constructed in the valley of Aravalies closing all the natural outlets. Due to rapid deforestation activities in the Aravalies sediment load in the lake is increasing year by year. Hydrology of the lake catchment is also changing. The lake thus created 420 years ago has been filled by sediment deposits to its present level.
Biodiversity	- Famous for its fish catches. Fishes from Jaismond lake are famous for their tastes. Fish from this lake is exported not only to other parts of the country but in most of the European and Western Countries. - Different types of migratory birds can be seen in the lake during different seasons of the year. - Several aboriginal tribes inhabit these islands in the lake and use locally made boats to ferry to different islands. These tribes depend on lake aquatic resources for their livelihood. They still live naked and use ancient form of weapon for hunting of fishes and other wild life.
Recreation	- One of the very important tourist centers of India. People from all over the country visit Jaismond lake to see the majestic lake and enjoy boating and fishing in the lake. - There are six beautiful Chatries on the earthen dam. There is a big Shiv Temple in the lake. - On the occasion of Shiv Ratri a big fair takes place - This lake is also called Dhebar lake.
Commercial use	For fish catch and also for irrigation purpose.
Studies undertaken	No study has been undertaken by any organization in India.
Governing authority	- Rajasthan State Government - Maharana of Mewar Memorial Foundation
General	The lake was constructed for providing drinking water to the local people and at the same time to create an aesthetic environment
Lake	Salt lakes of Rajasthan
Location	Sambhar lake, Phulera lake, and Didwana lake On the border of Jodhpur and Jaipur, 64 km to the west of Jaipur city 65 km to the north west of Sambhar is Didwana lake

Indian Lakes, Table 1 (Continued)

Location on map	Sambhar lies between 27°00' N latitude and 75°00' E longitude, Phulera lake lies between 27°12' N latitude and 74°34' E longitude, and Didwana lake lies between 26°52' N latitude and 75°11' E longitude
Climate	The climate of the lake region is tropical monsoon.
Altitude	360 m above mean sea level.
Surface area	Sambhar is the largest of the three lakes having an area of 23,300 ha and length of 32 km. The area of lakes Phulera and Didwana is about 200 ha each.
Inflow	Sambhar lake is fed by seasonal rivers Bandi, Medha, and several other streams. Water level of these lakes fluctuates from few centimeters to a maximum of 2 m. Sambhar lake often dries in early summer.
Outflow	All the three lakes are surrounded by sand flats and dry throne shrubs. Thus there is no outflow from the lakes
Type of lakes	Salt lakes of Rajasthan
Commercial use	About 7,800 ha of the eastern arm of Sambhar lake is devoted for salt production while 20% of Didwana lake is used as salt pans. The saline mud in Sambhar lake is 22 m deep and is underlain by a thin white crust of glistening common salt. The sediments below are saturated with brine. It is estimated that in the upper 4 m of the mud in the lake, whose average salt content is about 6%, there would be roughly 1 million tones of salt per square meter. Sambhar lake contains practically no magnesium salts. Potassium salts are absent in Didwana lake. Sodium Sulfate is present in Sambhar and Didwana.
Lake	Lonar lake in Maharashtra, India
Location	Situated at 140 km from Aurangabad, Lonar lake is a saltwater lake at Lonar in Buldana district, Maharashtra, India
Location on map	19°58'36"N 76°30'30"E
Climate	Semiarid climate. Annual average rainfall is around 700 mm.
Altitude	A series of low hills surround the basin which is oval in shape (almost round) with circumference at top of about 8 km (5 miles). The sides of the basin rise abruptly at an angle of about 75°. At the base, the lake has a circumference of about 4.8 km (3 miles). The slopes are covered with jungle interspersed with teak tree. A belt of large trees about a mile broad runs all-round the basin; belt is formed of concentric rings of different species of trees. A ring of date palms followed by a ring of tamarind trees (nearly 1.6 km or a mile broad) leads to a ring of babul trees, bounded on the inside by a belt of bare muddy space; mud space is several hundred meters/yards broad, devoid of all vegetation (due to soda content in the water), covered with a whitish slimy soil, and leads to the lake water. During the rainy season, the drainage into the lake covers the muddy space. The water of the lake contains various salts or sodas. During the dry weather, as the water level reduces with evaporation, large quantities of sodas are collected. A well of sweet water is also located on the southern side of the lake, close to lake's water edge
Surface area	Two small streams drain into the lake. Lonar lake has a mean diameter of 1.2 km (3,900 ft) and is about 137 m (449 ft) below the crater rim. The meteor crater rim is about 1.8 km (5,900 ft) in diameter. The circular depression bears a saline water lake in its central portion.
Inflow	There is underground feeding of the lake.
Outflow	Only through evaporation.
Type of lakes	• Lonar lake is the largest and oldest natural lake of meteor origin in the world. The lake is around 50,000 years old. The rim of the lake stands 5–6 m above the surrounding country, the trap appearing to dip away from the depression. • A lake that evolved in the resulting basaltic rock formation is both saline and alkaline in nature. • Profusion of aquatic life. • The chemical characteristics of the lake show two distinct regions that do not mix – an outer neutral (pH 7) and an inner alkaline (pH 11) each with its own flora and fauna. The lake is a haven for a wide range of plant and animal life. Resident and migratory birds such as black-winged stilts, brahminy ducks, grebes, shell-ducks (European migrants), shovellers, teals, herons, red-wattled lapwings, rollers or blue jays, baya weavers, parakeet hoopoes, larks, tailorbirds, magpies and robins and swallows are found on the lake. Among reptiles, the monitor lizard is reported to be prominent. The lake is also home to thousands of peafowls, chinkara, and gazelles. Plea to declare Lonar lake a protected wetland.
Ecological status	
Changes over the last years	• Mean depth of water in the lake of the order of 100 m is left only to about 50 m due to bottom being of highly weathered trap due to continued siltation in the lake. Underground feeding of the lake is bringing pollutant into the lake.
Recreation	• Center for all religious activities in Maharashtra

Indian Lakes, Table 1 (Continued)

Studies undertaken	• Geologists, ecologists, archaeologists, naturalists, and astronomers have reported several studies on the various aspects of this crater lake ecosystem. • The crater's age is usually estimated to be $52,000 \pm 6,000$ years (Pleistocene) (Geological Survey of India & Report, 1988), although a study published in 2010 gives an age of $656,000 \pm 81,000$ years. • The Smithsonian Institution, the United States Geological Survey, Geological Society of India, and University of Sagar and the Physical Research Laboratory have conducted extensive studies about the site. • Biological nitrogen fixation has been discovered in this lake in the year 2007. Nonsymbiotic nitrogen fixing microorganisms such as <i>Halomonas</i> sp., <i>Paracoccus</i> sp., <i>Klebsiella</i> sp., <i>Slackia</i> sp., and <i>Actinopolyspora</i> sp. have been reported from this lake. All the nitrogen fixers are haloalkaliphilic in nature as they can grow only at pH-11. Some of the bacteria and actinomycetes isolated from this lake are able to grow on some components of inorganic medium containing martian soil simulant components. • Maharashtra State Government
Governing authority General	Created by a meteor hitting the Earth during the Pleistocene Epoch. The lake is said to be the only crater in the great basaltic formation of India. The lake was initially believed to be of volcanic origin, but now it is recognized as an impact crater created by the hypervelocity impact of either a comet or a meteorite. The presence of plagioclase that has been either converted into maskelynite or contains planar deformation features (PDFs) has confirmed the impact origin of this crater. It is argued that only shock metamorphism caused by hypervelocity impact can transform plagioclase into maskelynite or create PDFs. The presence of shatter cones, impact deformation of basalt layers comprising its rim, shocked breccia inside the crater, and non-volcanic ejecta blanket surrounding the crater are further proofs of the impact origin of Lonar crater. As a result of the studies, broadly, the geological features of the Lonar crater has been marked under five distinguishable zones, exhibiting distinct geomorphic characteristics. The five zones are the following: 1. The outermost ejecta blanket 2. The crater rim 3. The slopes of the crater 4. The crater basin, excluding lake 5. The crater lake
Lake Location	Vihar lake, Mumbai, Maharashtra Vihar lake is located near Vihar village on the Mithi River within the precincts of the Borivali National Park, also called the Sanjay Gandhi National Park, in North Mumbai. By road, it is 31 km from Mumbai. Access by suburban electric train is to Kurla or Andheri and then by road. Access to the lake for the general public has been curtailed since March 13, 1993 (Source: Official BMC Board installed at the gate) following the Bombay Bombs on March 12, 1993 due to perceived threats to the Mumbai public, as the lake is located in the Sanjay Gandhi National Park.
Inflow	Impoundment of Mithi River, 20 km north of Mumbai, was effected to store the rainwater from a catchment area of 18.96 km^2 to create the Vihar lake. The Powai-Kanheri hill ranges form the catchment area, which drains the rainwater into the lake. For this purpose, three earthen embankment dams with a masonry spillway section were constructed to create a reservoir of 9,200 million gallons capacity at the full reservoir level of 80.42 m. The lake has a maximum water depth of 34 m and a minimum of 12 m. The lake's water spread area is 7 km^2. The dam height was raised in 1872 resulting in increase of water supply from 32 million gallons (catering to a population of 0.7 million) to 36 million gallons.
Biodiversity	Flora and fauna Mugger or Marsh Crocodile The lake and its catchment are protected by the Brihanmumbai Municipal Corporation and Sanjay Gandhi National Park Authority. The catchment areas of Vihar lake has high hills rising on all sides. The seclusion, protection, and security provided under the Sanjay Gandhi National Park have ensured well-wooded hill slopes and abundant natural regeneration. Higher percentage of khair species has been noted in the catchment area of the lake. As the lake is situated inside the Sanjay Gandhi National Park, the flora and fauna reported for the park would be relevant to the lake. However, freshwater crocodiles, Mugger or Marsh crocodiles (<i>Crocodilus palustris</i>), are known to inhabit the lake in sustainable numbers. As it is difficult to sight them in the lake, the park has set up a Crocodile Park to view the reptiles of different sizes.

Indian Lakes, Table 1 (Continued)

Commercial use	When built in 1860 (construction started in 1856), it was considered as the largest lake in Mumbai in the Salsette group of islands. It is hemmed between the Tulsi lake and the Powai lake (shown in map). It partly meets the drinking water needs of the South Mumbai region. It supplies only 3% of the Mumbai city's water requirement, after filtration at Bhandup where the large water filtration plant is located.
Studies undertaken	Limnological studies carried out by the Central Public Health Engineering Research Institute, Nagpur, India in 1964 indicated an unstable thermal stratification in the lake waters. The dissolved oxygen (DO) values were found to increase in some months and carbon dioxide was found to be less at the surface than at the bottom. In cooler season, the surface water was found to be less alkaline, which could be attributed to the photosynthesis activity of the algae. The pH stratification was found to be unstable. Interrelation was attributed to fluctuations in the chlorophyll, pH, and DO values; nitrates were generally absent on the surface and no sulfates were detected. Mahim Creek where Mithi River joins and where the sweet water episode occurred in 2006. In the year 2006, finding sweet water at the Mahim Creek (a semi-enclosed area), where freshwater and seawater meet, created a lot of excitement among the public. The health department of BMC who analyzed the water sample from the site found that salt level in the seawater was as low as 600 particles per million (ppm), compared to the normal level of 10,000 ppm. The National Institute of Oceanography, Goa, who were also consulted, stated that this phenomenon was not unusual and could have been caused by heavy rainfall and low tide. This necessitated the Maharashtra Government to intervene and examine the issue rationally to convince the excited public. BMC Commissioner gave a press statement stating: "The Mahim creek is located in a semi-enclosed area where freshwater and seawater mix especially during low tide, which caused the dilution. Also, the Vihar lake on the outskirts of Mumbai has been overflowing for the past few days and has flown into the Mithi River, which could be the reason for the water tasting sweet."
Governing authority General	The Brihanmumbai Municipal Corporation (BMC), a Government body With the few thousand wells feeding the population of Mumbai tending to go dry during summer, the acute shortage of water resulted in protests by the local residents in June 1845. A two-man committee, appointed by the British rulers of the time, to examine the grievances of the agitators concurred with water shortage problem and stressed the urgent need to solve the water supply problem of Mumbai. The Committee appointed by the government located suitable sites to construct dams and create reservoirs to store the monsoon flows of the Mithi river catchment, which resulted in the presently existing Vihar lake, Tulsi lake, and the Powai lake. Vihar reservoir was the first piped water supply scheme of Mumbai. In 1850, Captain Crawford submitted a report favoring the Vihar Scheme for the Mumbai city's water supply needs. Work on the "Vihar Water Works" commenced in January 1856 and was completed in 1860, during the governorship of John Lord Elphinstone (Cavazza, 1993). The Brihanmumbai Municipal Corporation (BMC) which controls the lake's affairs has also acquired agricultural land in the catchment area of the Vihar lake as a sanitary precaution.
Lake	Tulsi lake, Mumbai, Maharashtra
Location	Tulsi lake is in northern Mumbai, 32 km to the north of Mumbai by road. The nearest suburban electric train station is Borivli East on the Western Railways and is close to western express highway, with a further travel of 6 km from the station by road to the lake. The nearest Sahar International Airport is at a distance of about 20 km. As the lake is located inside the Sanjay Gandhi National Park, entry permits are to be obtained from the park authorities for visit to the lake. This is one of the three lakes located in the Salsette Island; the other two being Powai lake and Vihar lake. Both Tulsi lake and Vihar lake are located within the densely forested Sanjay Gandhi National Park or also known popularly as the Borivali National Park (BNP).
Location on map	19° 11' 24" N 72° 55' 04" E 19.1901° N 72.9179° E
Climate	The southwest monsoon sets in by mid-June and lasts till September. The maximum rainfall is normally recorded in the months of July and August. The mean annual rainfall is reported to be 2,500 mm.
Altitude	139.17 m above mean sea level
Surface area	Surface area of the lake is 1.355 km ² whereas the catchment area of the lake is 6.75 km ² . Average depth is 12 m with a gross storage at Full Supply Level (FSL) of 2,294 million gallons, out of which four million gallons per day are supplied to Greater Mumbai. The highest overflow level, recorded at the dam is 139.17 m (456.6 ft). This freshwater lake primarily fulfills the water requirement of the southern part of Mumbai.

Indian Lakes, Table 1 (Continued)

Inflow	Tulsi lake was built by damming the River Tasso, and redirecting the flow to the nearby Vihar lake. Rainwater from the catchment area of 676 ha of Powai-Kanheri hill ranges drains into the lake.
Outflow	During rainy season the flood flows into the Powai lake and further down in to the Mithi River.
Type of lakes	A freshwater lake
Ecological status	The vegetation on the hill slopes draining into the lake is thick and lush, undisturbed, and of mixed moist deciduous type.
Biodiversity	As the lake is situated inside the Sanjay Gandhi National Park, the flora and fauna reported for the park would be relevant to the lake. However, freshwater crocodiles, Mugger or Marsh crocodiles (<i>Crocodilus palustris</i>), are known to inhabit the lake in sustainable numbers. As it is difficult to sight them in the lake, the park has set up a Crocodile Park to view the reptiles of different sizes.
Recreation	For tourists.
Commercial use	It is stated to be the second largest lake in Mumbai and supplies part of the city's potable water.
Governing authority	The lake and its catchment are protected by the Brihanmumbai Municipal Corporation and Sanjay Gandhi National Park Authority.
Lake	Powai lake, Mumbai, Maharashtra
Location	Powai lake (named after Framaji Kavasji Powai Estate) is situated in the northern suburb of Mumbai, in the Powai valley, where a Powai village with cluster of huts existed. Powai lake is located downstream of the Vihar lake on the Mithi River.
Location on map	19°08'N 72°55'E/19.13°N 72.91°E
Altitude	58.5 m
Surface area	Catchment area is 6.61 km ² .
Type of lakes	An artificial lake
Changes over the last years	The city suburb called Powai shares its name with the lake. Indian Institute of Technology, Bombay, one of the premier institutions of science and technology in India, is located to the east of the lake. Another famous institution, the National Institute of Industrial Engineering (NITIE) is also located close to the lake. Housing complexes and plush hotels are developed all around the lake periphery. Population around the lake has thus substantially increased over the years. When it was built, the lake had a water spread area of about 2.1 km ² (520 acres) and the depth varied from about 3 m (9.8 ft) (at the periphery) to 12 m (39 ft) at its deepest. The Powai lake has gone through many stages of water quality degradation. The lake water which used to supply to Mumbai for drinking water has been declared unfit to drink. The lake still remains a tourist attraction.
Lakes of Eastern India	
Lake	Chilka lake in Orissa, India
Location	Situated at 150 km south west of Cuttack, Orissa, India
Location on map	19°43'N 85°19'E/19.717°N
Climate	A tropical monsoon climate prevails over the drainage basin area of the lake. The lake experiences Southwest and Northeast monsoons during June to September and November to December, respectively, with average annual rainfall of 1,238.8 mm (48.77 in.), with 72 rainy days. The maximum temperature of 39.9°C (103.8°F) and minimum temperature of 14°C (57.2°F) have been recorded. The wind speed varies from 5.3 to 16 m (17–52 ft)/h with southerly and southwesterly direction due to the influence of the Southwest monsoon and from north and north easterly direction during the rest of the months.
Altitude	0–5 m. above mean sea level
Surface area	Maximum area of the lake is 1,165 km ² (450 miles ²) and minimum area of the lake is about 740 km ² (286 miles ²). Catchment area of the lake is 3,560 km ² (1,370 miles ²). Maximum depth is 4.2 m (13.8 ft), water volume is 4 km ³ (3,200,000 acre·ft), and surface elevation is 0–2 m (6.6 ft).
Inflow	35 streams including the Bhargavi, Daya, Makra, Malguni, and Nuna rivers' inflow rate of the silt into the lake is about 13 million tones per year. Water volume is 4 km ³ (3,200,000 acre·ft).
Outflow	Old mouth at Arakhakuda, new mouth at Satapada to Bay of Bengal
Type of lakes	Large, shallow, pear-shaped, brackish natural lake, separated from Bay of Bengal by a 200-m high sandy ridge which is 71-km long and 32-km wide.
Ecological status	The lake has numerous islands. The larger islands, separated by shallow channels, lie between the barrier and the main body of the lake. A total 42 km ² (16.2 miles ²) of channels connect the lake with Bay of Bengal. The six major islands are Parikud, Phulbari, Berahpura, Nuapara, Nalbana, and Tampara. These islands, together with the peninsula of Malud, constitute the Krishnaprasad Revenue Block of Puri District.

Indian Lakes, Table 1 (Continued)

Changes over the last years	• Due to siltation the width of the barrier has fluctuated and the mouth to the sea has periodically been closed. The location of the mouth has also frequently shifted, generally toward the northeast. The mouth, which was 1.5 km (0.9 miles) wide in 1780, was only 75 km (0.5 miles) 40 years later. The local fisherfolk, to maintain their livelihood, had to cut open the mouth regularly to gain access to the sea for fishing. • The lake is shrinking due to shore area of the lake being reclaimed for prawn effluents. • Inflow rate of the silt into the lake is about 13 million tonnes per year due to which the lake is shrinking.
Biodiversity	• Chilika lake is the largest wintering ground for migratory birds, on the Indian subcontinent. It is one of the hot spots of biodiversity in the country. Some species listed in the IUCN Red List of threatened animals inhabit the lake for at least part of their life cycle, which are white bellied sea eagles, greylag geese, purple moorhen, jacana, herons and flamingos, Egrets, Gray and Purple Herons, Indian Roller, Storks and White Ibis, Spoonbills, Brahminy Ducks, Shovellers and Pintails, and more. Migratory waterfowl arrive here from as far as the Caspian Sea, Baikal lake, and remote parts of Russia, Mongolia, Lakah, Siberia, Iran, Iraq, Afghanistan, and from the Himalayas. A census conducted in the winter of 1997–1998 recorded about two million birds in the lake. • Other than the birds, Chilka's shores are home to blackbuck, spotted deer, golden jackals, and hyenas, and the lake is rich in aquatic life – its waters harbor around 160 species of fish, crustaceans and other marine creatures, including the famous Chilka dolphin. Prawn, crab, and mackerel fishing are an important source of livelihood for the local people, and hundreds of small fishing boats set sail each morning to bring in the day's catch from the lake. The Nilgiri Biosphere Reserve harbors India's second largest pachyderm population, and the chances of seeing elephant herds is pretty high, especially during the dry season.
Recreation	The lake was declared the wetland of international importance in 1981 under the Ramsar Convention. Lots of migrating birds visit Chilka every year. Chilka bird sanctuary has been established.
Commercial use	The lake is used mainly for fishing.
Studies undertaken	Limnological and ecological studies
Governing authority	Chilka Lake Development Authority
General	• The Chilka lake in Orissa is Asia's largest inland saltwater lagoon. Studded with small islands – including the picturesquely named Honeymoon Island and Breakfast Island – the lake is separated from the Bay of Bengal by a sandy ridge. The pear-shaped lake spreads across 1,100 km² and has a unique ecosystem with a range of aquatic flora and fauna found in and around its brackish waters. An impressive array of bird life, both native and migrant, makes Chilka one of the best places in India for a bit of satisfying bird-watching. White bellied sea eagles, greylag geese, purple moorhen, jacana, herons, and flamingos are among the many species which make the lake a bird watcher's delight: Chilka, in fact, is home to one of the world's largest breeding colonies of flamingos. • Chilika lake is a shallow bar built estuary with huge areas of mudflats. The western and southern margins of the lake are fringed by the Eastern Ghats hill range. • Several inland rivers, which bring silt into the lake, control the northern end of the lake. A 60-km (37 miles) long barrier beach called Rejhansa, formed by northerly currents in the Bay of Bengal resulted in the formation of this shallow lake and forms its eastern side. As an ephemeral lake its water surface area varies from 1,165 km² (449.8 miles²) in the summer monsoon season to 906 km² (349.8 miles²) in the winter dry season. • The mean depth of water in the lake varies from 0.9 to 2.6 m in dry season and 1.8 to 3.7 m in monsoon season.
Lake	Rabindra Sarobar, Kolkata, West Bengal
Location	Rabindra Sarobar (previously known as Dhakuria lake) is in south Kolkata in the Indian state of West Bengal. It is popularly referred to as the "Lungs of Calcutta." The name also refers to the area surrounding the lake. It is flanked by Southern Avenue to the North, Russa Road to the West, Dhakuria to the East, and the Kolkata Suburban Railway tracks to the South. Rabindra Sarovar is 30 km away from Dum Dum airport and 12 km from the Howrah railway station. The area is served by the Rabindra Sarobar station of the Kolkata Metro and lake Gardens and the Tollygunge station of the Kolkata suburban railway (Budge Budge section). It is one of the two points where the two railway systems interface (the other being Dum Dum).
Surface area	73 acres (300,000 m ²) are covered by water, while shrubs and trees, some of which are more than 100 years old, occupy the rest of the area.
Type of lakes	It is an artificial lake.

Indian Lakes, Table 1 (Continued)

Changes over the last years	Like a majority of artificial lakes in the country, Rabindra Sarovar is suffering environmental degradation. Water pollution is on the rise, owing to an increase in tourist flow and habitation around the lake. The Ministry of Environment and Forests, Government of India, has recently included this lake under the National Lake Conservation Plan in the hope that this will help preserve it. The local authorities have also begun an extensive tree plantation program.
Biodiversity	In the winter, one can spot some migratory birds around the lake, though the numbers are dwindling because of the rise in pollution level. The lake itself is home to many varieties of fish. Fishing is strictly prohibited.
Recreation	Today the lake and its surrounding areas are one of the most popular recreational areas in Kolkata. The area around this excavated lake was later developed to build recreational complexes, which included children's parks, gardens, and auditoria. A number of people come for a walk around the lake in the mornings to enjoy the fresh air. Many visit the sunrise point to offer their prayers to the Sun. During the day, it is visited by families on a picnic, tourists, young lovers, and joggers.
Commercial use	There is an auditorium or a hall within the sarovar complex which adjoins the Rabindra Sarovar Stadium. Its name is Pavilion Hall. A number of rowing and swimming clubs are situated within the Rabindra Sarovar complex. While the former are located to the north of this lake, the latter are located to its south. In 1858, the British founded the Calcutta Rowing Club (CRC), presently one of the oldest clubs in India, to promote rowing activities in Kolkata. In 1901, it got affiliated to the prestigious Amateur Rowing Association of the East (ARAE) and in 1923 signed a reciprocal arrangement deal with the London Rowing Club. The CRC has been the hub of competitive rowing in Kolkata for more than 150 years and has organized many intra- and inter-club competitions. Rowing facilities are available to members on a regular basis, from 6 a.m. to 7:30 a.m. and from 3:30 p.m. to 5 p.m. The Bengal Rowing Club, Lake Club, and Calcutta University Rowing Club are a few other rowing clubs located in the Rabindra Sarovar complex. One of the most prestigious and oldest swimming clubs in Kolkata, the Indian Life Saving Society (formerly known as Anderson Club) has its office in the lake complex.
Governing authority	Calcutta Improvement Trust (CIT)
General	In the early 1920s, the Calcutta Improvement Trust (CIT), a body responsible for developmental work in the Kolkata metropolitan area, acquired about 192 acres (0.78 km ²) of marshy jungles. Their intention was to develop the area for residential use – improving the roads, raising and leveling some of the adjacent land, and building lakes and parks. Excavation work was undertaken with the plan of creating a huge lake. Originally known as Dhakuria lake, in May 1958, CIT renamed the lake as Rabindra Sarovar, as a tribute to the great Bengali writer and Nobel Laureate, Rabindranath Tagore. Like a majority of artificial lakes in the country, Rabindra Sarovar is suffering environmental degradation. Water pollution is on the rise, owing to an increase in tourist flow and habitation around the lake. The Ministry of Environment and Forests, Government of India, has recently included this lake under the National Lake Conservation Plan in the hope that this will help preserve it. The local authorities have also begun an extensive tree plantation program.
Lakes of North-Eastern India	
Lake	Loktak lake in Manipur
Location	Near Moirang in Manipur state, India.
Location on map	24°33'N 93°47'E
Climate	Tropical Monsoon Climate. With an average annual rainfall of 1,183 mm (46.57 in.) tropical monsoon climate prevails in the valley. Temperatures range from 0°C to 35°C (32–95°F). February and March are the driest months.
Altitude	770 m above mean sea level
Surface area	Surface area 287 km ² (111 miles ²) Max. length 35 km (22 miles) Max. width 13 km (8 miles) Average depth 2.7 m (8.9 ft) Max. depth 4.6 m (15.1 ft) Surface elevation 768.5 m (2,521 ft)
Inflow	The river Loktak and its tributaries, which flowed at much lower level in the past, were dammed when an earthquake raised a barrier and closed its outlet. The lake thus created was filled with alluvia to its present level, leaving the lake in its part. The lake is connected to Imphal River by a 10-km long natural course known as Khordak Cut. Water exchange between the lake and Imphal river takes place depending upon water level of the lake and river.
Outflow	Runoff from the surrounding hill from three sides feed the lake. Ungamel Channel (Ithai Barrage) is its only outlet now. Through barrage for hydropower generation, irrigation, and water supply

Indian Lakes, Table 1 (Continued)

Type of lakes	The largest freshwater lake in northeastern India, also called the only Floating lake in the world due to the floating phumdis (heterogeneous mass of vegetation, soil, and organic matters at various stages of decomposition) on it
Ecological status	During non-rainy season, inflow to the lake brings domestic sewage, fertilizers, and pesticides. Due to eutrophication and siltation, vast portion of the lake has been covered by thick algae locally called Phumdi due to which power production from the lake is suffering. Profusion of aquatic vegetation. Famous for its floating mass called phumdi. Phumdi in the lake being the only refuge of the endangered Sangai (meaning “the one that looks at you”), Manipur brow-antlered deer (the most endangered species in the wild), Hog Deer, Common Otter, Large Indian Civett, Small Indian Civett, and Indian Wild Bear.
Changes over the last years	Maximum depth of water in the lake is about 20 m and minimum depth of water in some part of the lake is about 5 m. The lake is shrinking fast. Maximum depth of lake has reduced from 29 m in 1950 to about 20 m in 1980. It had vast area of 2,000 km ² in 1950 that reduced to 495 km ² in 1971 and 289 km ² in 1995.
Biodiversity	Encroachment is also for reclamation of land for agriculture, socioeconomic activity. It is a wetland of international importance included in RAMASAR Convention. • The enormous quantities of vegetable matters decaying in the swamps make them high capacity fertilizer factories releasing large quantities of fish food. • About 172 macrophytes species – 14 floating, 15 submerged, 5 rooted floating, 25 shallow water species, 25 habitats in the marginal areas, and 65 composing the phumdi. • Migrating waterfowl. Enormous flocks of ducks and geese. Of the 51 species recorded in recent times, migratory birds constitute about 24%. Several species of migratory birds also bypass Loktak as a wintering area. • Designated as “Jewel of Switzerland” of India due to its biological richness and uniqueness of habitat.
Commercial use	• The lake is the lifeline of Manipur Valley. The lake is used for domestic purpose, irrigation, power generation, fishing, and navigation. The Loktak Hydroelectric Project is running by constructing Ithai Barrage on the Khordak Cut. There is a hydropower plant of 10 MW being operated by lake water. Lake area is about 26,000 ha. • Enormous fish resources support large fishing communities in and around the lake area. About 60% of the fish catch of Manipur comes from Loktak alone. • Tourist inflow is mostly from East Asian Countries due to its proximity to East Asia. • This ancient lake plays an important role in the economy of Manipur. It serves as a source of water for hydropower generation, irrigation, and drinking water supply. The lake is also a source of livelihood for the rural fisherman who live in the surrounding areas and on phumdis, also known as “phumshongs.” Human activity has led to severe pressure on the lake ecosystem. Fifty-five rural and urban hamlets around the lake have a population of about 100,000 people.
Studies undertaken	• Limnological study by Manipur University • Preliminary field investigation for hydrological study by National Institute of Hydrology, Roorkee
Governing authority	• Manipur State Government • Loktak Lake Development Authority • WWF (World Wild Fund) is also active for the lake
General	Serious threat from pollution and encroachment. Considering the ecological status and its biodiversity values, the lake was initially designated as a wetland of international importance under the Ramsar Convention on March 23, 1990. But the lake was designated by the Ramsar Convention under the Montreux Record on June 16, 1993, for the reason of keeping a record of Ramsar sites where changes in ecological character have occurred, are occurring or are likely to occur.
Lake	Deepar Beel in Assam
Location	Situated at a distance of 10 km southwest to Guwahati, Assam, India
Location on map	26.13°N 91.66°E
Climate	Tropical humid monsoon climate with annual average rainfall of 1,800 mm. Temperatures in the beel vary from 10°C to 32°C. During the winter months, when the size of the lake reduces in area by about 50%, the shore area (up to 1 km) is cultivated with rice paddy when the climate is also relatively cool and dry. The tropical monsoon climate prolongs from May to September when it is humid. Pre-monsoon showers are experienced between March and May.
Altitude	53 m above mean sea level
Surface area	Lake area is about 4,000 ha. Depth of water at maximum flooding is about 4 m which drops down to 1 m in dry season. The Beel has a perennial water spread area of about 10.1 km ² , which extends up to 40.1 km ² during floods. However, an area of 414 ha has been declared as “Deepor Beel Sanctuary” by the Government of Assam. As per a Remote Sensing Study the wetland area is reported to have reduced to 14.1% (405 ha) from 1990 to 2002.

Indian Lakes, Table 1 (Continued)

Inflow	The Basistha and Kalmani rivers and local monsoon runoff are the main sources of water to the lake, between May and September. Khonajan channel drains the beel into the Brahmaputra river, 5 km to the north. It acts as a natural stormwater reservoir during the monsoon season for the Guwahati city (stated to be the only major storage water basin for the city's drainage, with about 4 m depth of water during monsoon dropping to about 1 m during the dry season.
Outflow	To river Brahmaputra
Type of lakes	A natural freshwater lake
Ecological status	The hydrophytic vegetation of the beel has been classified, based on ecological adaptation, into the following categories with their floristic elements (MAPCOST Report, 1996): Aquatic vegetation like water hyacinth, aquatic grasses, water lilies, and other submerged, emergent, and floating vegetation are found during the summer season. In the dry areas, during winter, aquatic and semi-aquatic vegetation are seen. In deep open water area, marshy lands, mud flat, emergent vegetation, water hyacinth patches, and net-grass land patches are reported. Migratory waterfowl, residential waterfowl, and terrestrial avifauna are common in paddy field areas, dry grassland areas, and scattered forest areas. A total of 18 genera of phytoplankton are reported from the core area of the Beel ecosystem out of which species of <i>Oscillatoria</i> and <i>Microcystis</i> are dominant.
Changes over the last years	Half of the lake dries in winter and the shore line is converted to rice fields. Due to this there is continuous encroachment by the farmers resulting in shrinkage of the lake. Forest to the south of the lake is being felled due to which heavy sediment load is coming into the lake resulting in its shrinkage. Natural and anthropogenic causes for the deterioration of the beel are many. The major reasons reported in the beel ecosystem are the following: • Proliferation of human settlements, roads, and industries around the periphery (in the eastern and northeastern sides) causing pollution problems • Wastewater from different parts of the city and the adjoining areas • Construction of broad-gauge railway line on the periphery of the beel • Allotment of the government vacant land to private party by Government settlement department • Brick kilns and soil cutting • Hunting, trapping, and killing of wild birds and mammals • Unplanned intensive fishing practices (both during day and night)
Biodiversity	The beel is a natural habitat to many varieties of birds. Birds of 219 species including more than 70 migratory species are reported in the beel area. The largest congregations of aquatic birds can be seen, particularly in winter, with a reported recorded count of 19,000 water birds in a day. Some of the globally threatened species of birds are Spot-billed Pelican (<i>Pelecanus philippensis</i>), Lesser Adjutant Stork (<i>Leptoptilos javanicus</i>), Baer's Pochard (<i>Aythya baeri</i>), Pallas' Sea Eagle (<i>Haliaeetus leucogaster</i>), Greater Adjutant Stork (<i>Leptoptilos dubius</i>), etc. Surveys have revealed 20 amphibians, 12 lizards, 18 snakes, and 6 turtle and tortoise species in the beel. Over 50 commercially viable species of fish belonging to 19 families have been identified, which supplies stock to other nearby wetlands and rivers. The beel provides food, acts as a spawning and nursery water body; some of the species breed within the beel. Spot-billed pelican found in beels and lakes in India. Among the large number of migratory waterfowl, the Siberian crane (<i>Grus leucogeranus</i>) regularly migrates to this habitat during its annual journey. This is in addition to the large congregation of residential water birds seen in the lake.
Commercial use	Considering the richness of the bird varieties found in the beel, the Birdlife International has declared Deepor Beel as an Important Bird Area (IBA) with high priority for conservation. The inhabitants around the villages located in the periphery and the catchment of the beel use the beel for the following: • Fishing • As waterway for transporting the villagers of the southern boundary to the NH 37 • Collecting fodder for domestic cattle and collecting aquatic seeds such as Giant water lily, <i>Nymphaea</i> sp., etc. • Raising Boro paddy – sown in December–January and harvested during April–May

Indian Lakes, Table 1 (Continued)

Studies undertaken	The Ramsar Convention, which has recognized the Deepor Beel in its list of 1,782 wetland sites, with 158 Contracting Parties to the Convention of the world and holds seminars to create awareness of the beel's uniqueness. Aaranyak, an NGO organization set up to foster conservation of biodiversity in Northeast India through research, environmental education, capacity building, and advocacy for legal and policy reforms to usher a new era of ecological security is actively involved in Community Based Conservation Projects, which include among other projects the "Deepor Beel Community Conservation Project." The project was designed to reduce the anthropogenic pressure on the wetland by providing for alternative and diversified means of livelihood to the people living along the fringe villages. The purpose of the project is to set up some community run "Self-Help Groups" (SHGs) to strengthen their livelihood options through diverse means and gain their support in the conservation of Deepor Beel as wetland ecosystem. North Dakota State University, USA, has a website created as a tool to facilitate better understanding of the concepts and practices in environmental management, and to complement the graduate course materials for the students who undertook a "Case Study of Deepor Beel Wetland Management" for the fall course of 2007. The Animal Ecology Laboratory in the Department of Zoology, Guwahati University has been involved in biological studies of the beel.
Governing authority	• Deepar Beel Bachao Samiti. • Fisheries Department, Government of Assam, India
General	<i>Guwahati Water Bodies (Preservation and Conservation) Bill, 2008</i> Due to serious threat from pollution and encroachment, The Guwahati Water bodies (Preservation and Conservation) Bill, 2008 has been passed with the objective of preserving the wetland, minimizing the problem of waterlogging in the city and creating an eco-friendly atmosphere. With this Bill at its command, the Government of Assam is planning to reacquire land in the periphery of Deepor Beel, to undertake development projects, including water sports at the beel, and for this purpose a budgetary allocation of about US\$3 million (Rs.12 crores) has been approved.
Lake	Rudrasagar (Lake) in Tripura, India
Location	Situated 55 km west of City of Agradala in Tripura, India
Location on map	23.13°N 90.66°E
Climate	Tropical humid monsoon climate with annual average rainfall of 2,500 mm, with 4/5 flood peaks. The tropical monsoon climate prolongs from May to September when it is humid. Pre-monsoon showers are experienced between March and May. Temperature variation in and around the lake is from 37°C to 50°C.
Altitude	53 m above mean sea level
Surface area	About 6 km ² , maximum depth of water in the lake is about 6 m. Lake water is fresh with insignificant pollution with a depth varying from 2 m to 9 m. Fluctuation in water level varies from EL 9 m to 16 m.
Inflow	The lake receives flow from three perennial streams, namely, Noacherra, Durlavnaraya cherra, and Kemtali cherra. Substantial base flow in streams around the year.
Outflow	After settling the sediment from the received flow, clear water discharges into the River Gomati through a connective channel, namely, Kachigang. Lake outflow is controlled by sluice gates.
Type of lakes	Hydromorphologically, Rudrasagar lake is a natural sedimentation reservoir. The lake bed has been formed by silt deposition. As such no rock formation is found with 50 m being silt (Clay loam) deposition and below formation is sandy. Surrounding hillocks are of soft sedimentary formation. The soil in lake area is silty clay loam to clay loam.
Ecological status	Input to the lake is monsoon runoff from the catchment area bringing debris from the urban land and sediment from exposed agricultural field. • Night soils and other sewage from Agartala is dumped into Rudrasagar. These wastes provide biomass which is helpful for the fish population. • More than 200 macrophytes species • Profusion of aquatic vegetation
Changes over the last years	Water spread area of the lake has reduced to about 6 km ² from 12 km ² in 1950. Maximum depth of water has reduced to 6 m from 20 m in 1950. The lake and its catchment area of the lake has been encroached by planners and developers.
Biodiversity	• Migrating waterfowl. Enormous flocks of ducks and geese. • Several species of migratory birds mostly from eastern countries bypass Rudrasagar lake during different seasons of the year. Enormous fish resources support large fishing communities in and around the lake area. About 50% of the fish catch of Tripura comes from Rudrasagar alone.

Indian Lakes, Table 1 (Continued)

Recreation	In 1980, the erstwhile King of Tripura, Bir Bikram Kishore Manikya Bahadur built a magnificent water palace in the midst of Rudrasagar lake, called Neermahal. It served as his summer residence. It is Northeast India's only water palace. This palace "Neer Mahal" is similar to "Lake Palace" in Pichola lake at Udaipur. Basement of Neer Mahal was under water, but it now stands exposed to open air.
Commercial use	Lake water is used for fishing, recreation, tourism, and irrigation. • A palace, "Neer Mahal," was constructed inside Rudrasagar by ruling king during the eighteenth century. This palace "Neer Mahal" is similar to "Lake Palace" in Pichola lake at Udaipur. Basement of Neer Mahal was under water, but it now stands exposed to open air. • Major fairs are held on the bank of this lake.
Studies undertaken	Though pollution and encroachment is threatening the lake, no hydrological study has been taken on this lake.
Governing authority	• Fishery Department, Kunjvan, Agartala • Tripura University, Surjamani Nagar • Rudrasagar Udbastu Fisherman Samanayvay Samiti Ltd., Melaghar, Rajghat
General	The lake has faced the problem of pollution due to the following reasons: • The non-point sources of pollutant such as agricultural runoff, anthropogenic introduced solid and semisolid pollutants • Malpractices such as anthropogenic dumped garbage, deposition of solid waste and construction materials along the shoreline, etc. • Eutrophication, an uncontrolled growth of alien invasive species such as water hyacinth, excessive algae was observed in the lake which caused loss of aquatic biodiversity • Agricultural activity (use of pesticides and fertilizers) in the area adjacent to the lake • Deforestation, filling, draining and degradation of wetland areas: Clearing and removal of native vegetation due to the rapid unplanned urbanization, rural or industrial development • Lack of awareness, scientific knowledge and negligence in protection by law • Competition for using lake water such as for drinking, irrigation, fishing, etc. • Untreated or inadequately treated domestic and industrial effluents from point sources located all over the basin. • Cultural siltation in the form of immersion of idols during specific festivals, an annual feature in India, has been a source of serious metallic pollution of lakes. • Not having a definite Wetland Authority, Special Purpose Vehicles (SPVs) for Lake Management and conservation with a unified mandate have not been set up. • Lack of community toilet facilities around periphery of the lake. Ownership and legal status of the lake and the inhabitants around the lake are not clearly defined. Major soil erosion in catchment area of the lake is one of the major problems to decrease the lake area and to decrease the depth of the lake also. Such degradation in catchment area and siltation in the lake has the effect since long time in the lake. For such reason and others, the area of Rudrasagar lake has been decreased drastically from 1,000 ha prior to 1950 to more or less 100 ha at present. Silting of lakes on account of increased erosion as a result of expansion of urban and agricultural areas, deforestation, flood, immersion of idols by the religious activity and such other land disturbances taking place in the drainage basin of the lake. The Government of India's Ministry of Environment and Forest has identified Rudrasagar as one of the wetlands of National Importance for conservation and sustainable use based on its biodiversity and socioeconomic importance. Secretary General, convention on wetlands, Ramasar site has declared Rudrasagar lake as wetland of international importance and it has been included in the list of wetlands of International Importance.
Lake	Barapani lake, Meghalaya
Location	Umiyam lake, also known as Barapani (Big Water) is a spot around 15 km from Shillong where a massive hydroelectric dam has been constructed across the Umiyam river stream.
Location on map	
Climate	Temperature in summer varies from 15°C to 30°C, and in winter from 4°C to 24°C. Average annual rainfall is around 2,000 mm.
Altitude	1,525 m above mean sea level.
Recreation	The lake is popular for Water Sport and adventure facilities that it offers. Kayaking, Water cycling/scooting, and boating are a few of the facilities available at the Umiyam lake. The lake has been developed as a tourist spot by the State authorities and the Meghalaya Tourism Department runs the Orchid Tourist home overlooking the lake.
Governing authority	Government of Meghalaya

Indian Lakes, Table 1 (Continued)

General	Shillong, the capital of Meghalaya takes its name from the deity Shyllong or Lei Shyllong. This city used to be the capital of Assam for over century since 1874 till Meghalaya became a separate state. The city is based on an elevated swath which lays almost 1,500 m above the sea level. The city is picturesquely located within the Umiang ravine from north and the Diengiei hills from the northwest making this city a prey to natural blessings as well as vagaries (incessant rains during June–September). One such incident almost wiped out Shillong from the face of earth in 1897 when a strong earthquake destroyed the city. The hard working people of Meghalaya reconstructed the city completely. Shillong was born in the laps of nature and offers every one of its bequeathed element for exploration to the wanderlust. The amazing series of waterfalls, the mystic mountain peaks, crystal clear water lakes, breathtakingly beautiful golf courses, museums, and zoo; Shillong has a different façade for everyone. Though the weather Gods remain aloof during peak winters and summers, the region offers its best face in March, April, September, and October not necessarily in that sequence.
Lakes in Central India	
Lake	Upper Bhopal lake in Madhya Pradesh
Location	The largest artificial lake in Asia which lies on the Western side of the capital city of Madhya Pradesh, Bhopal, India
Location on map	23.25°N 77.34°E
Climate	Semiarid climate. Annual average rainfall in the catchment area is about 1,100 mm.
Altitude	508 m above mean sea level.
Surface area	Presently lake area is about 36 km ² , maximum depth of water in the lake is about 10 m, and minimum depth of water in the lake is about 3 m. In dry season, the lake water surface area even reduces to 5 km ² .
Inflow	Catchment area is 361 km². • From river Kolans. • During rainy season, inflow to the lake brings domestic sewage, fertilizers, and pesticides into the lake. • Due to dense population on the fringe area of the lake non-point source of pollution brings domestic sewage, industrial wastes into the lake throughout the year.
Outflow	Lake is connected to Betwa River by a minor river Kalisot into which the spillway from the lake is discharged. Overflow from the lake is controlled by 11 numbers of spillway gates.
Type of lakes	A man made freshwater lake, constructed 1,100 years ago. The lake was built by damming of river Kolans between Shyamla Hills by constructing earthen dam.
Ecological status	The Upper Bhopal lake has been declared Wetland of International Importance and included in RAMSAR Convention.
Changes over the last years	• The lake is shrinking at a fast pace. It had vast area of 1,800 km² spread up to Bhojpur at the time of construction 1,100 years ago. Mughal emperors reclaimed most parts of the lake for agriculture by putting earthen dam at Kamla Park. Lake area of about 195 km² in 1671 has got reduced to just about 30 km² by the year 2000. • It was once a vast lake that has been filled by clay sediment deposits. The present lake and associated water bodies are remnants.
Biodiversity	• “Van Vihar,” an open wild animal zoo is on the fringe of the Upper Bhopal Lake supporting wildlife. • Profusion of aquatic vegetation. • Famous for its deep-rooted tall aquatic plants which are uprooted and used by local populace for fuel requirement. • About 52 macrophyte species – 4 floating, 25 submerged, 23 deep rooted. Aquatic vegetation is shown in the photographs. • In recent times, migratory birds constitute about 54%. Of the bird population several species of migratory birds also bypass Upper Bhopal lake as a wintering area. • The enormous quantities of vegetable matters decaying in the swamps make them high capacity fertilizer factories releasing large quantities of fish food. • Enormous fish resources support large fishing communities in and around the lake area. About 70% of the fish requirement of City of Bhopal is fulfilled by catch of fish from the Upper Bhopal lake.
Recreation	• Encroachment is for reclamation of land for agriculture, socioeconomic activity, and urban development. Major encroachment in the water surface area of the lake is by the state government for creating transport facilities for VIP, recreational activities, etc. Now the local government authority is the major encroacher for creating several facilities. They are moving inward for constructing infrastructural facilities. • Tajul Masjid, one of the famous masjids in Asia, is situated in Bhopal. Annual fair of “IZETMA” is held every year in this masjid. A congregation of more than 150,00,000 people takes place during this festival. People from different countries visit Bhopal during this festival.

Indian Lakes, Table 1 (Continued)

Commercial use	For fishing, supply of drinking water, and water sports. An important center for tourism. It is a major source of potable water for the residents of the city, serving around 40% of the residents with nearly 30 million gallons per day. Bada talaab, along with the nearby Chhota Talaab, meaning small lake in Hindi, constitute Bhoj Wetland, which is now a Ramsar site.
Studies undertaken	• Limnological study by Barkatulah University, Bhopal. • Water quality study was undertaken under Bhoj Wetland Project. • Hydrological studies have been conducted by National Institute of Hydrology, Roorkee.
Governing authority	• Madhya Pradesh State Government • Nagar Nigam, Bhopal
General	• Upper Bhopal lake (Bhojtal) was built by Raja Bhoj during his tenure as a king of Malwa (1005–1055). He established the city of Bhopal (also named after him, then as Bhojpal) to secure the eastern frontier of his kingdom. The lake was created by constructing an earthen dam across the Kolans River. An 11-gate dam called the “Bhadbhada dam” was constructed at Bhadbhada in 1965 at the southeast corner of the lake, and now controls the outflow to the River Kaliasote. • Upper Bhopal lake is situated on the west central part of Bhopal city and is surrounded by Van Vihar National Park on the south, human settlements on the east and north, and agriculture fields on the west. It has an area of 31 km², and drains a catchment or watershed of 361 km². The watershed of the Upper lake is mostly rural, with some urbanized areas around its eastern end. The Kolans was formerly a tributary of the Halali River, but with the creation of the lake using an earthen dam and a diversion channel, the upper reach of the Kolans River and Bada Talaab now drains into the Kaliasote River. • Since the construction of the lake in the eleventh century, Bhopal city has grown around it. The people are religiously and culturally attached to the lakes. The lakes meet their needs of water supply and they wash clothes in them (very harmful for the lake ecosystem), cultivate water chestnut in Bhojtal and lotus in Chhota Talaab. The idols of gods and goddesses are also immersed in the lake during religious festivals, though the local administration is advising devotees not to do so. The Takia island in Upper lake has a tomb of the Shah Ali Shah Rahamatullah Alla, which has religious and archaeological significance.

Lakes of Southern India

Lake	Kolleru lake in Andhra Pradesh
Location	Kolleru lake is located in Andhra Pradesh state, India. Kolleru is located between Krishna and Godavari deltas. Nearest city is Vijayawada, which is 65 km by road or rail. Nearest town is Eluru. Kolleru spans into two districts – Krishna and West Godavari.
Location on map	16°39'N 81°13'E to 16.65°N 81.217°E
Surface area	245 km ²
Inflow	The lake serves as a natural flood-balancing reservoir for these two rivers. The lake is fed directly by water from the seasonal Budameru and Tammileru streams, and is connected to the Krishna and Godavari systems by over 68 inflowing drains and channels.
Type of lakes	A large freshwater lake
Ecological status	Grey Herons, Egrets, Painted Storks, and Black-headed Ibises gather in thousands during sunset at Kolleru lake, Andhra Pradesh, India. Rich in flora and fauna, it attracts migratory birds from Northern Asia and Eastern Europe between the months of October and March. During this season, the lake is visited by an estimated 20,00,000 birds. The resident birds include Grey pelicans, Asian Open-billed Storks (<i>Anastomus oscitans</i>), Painted Storks (<i>Mycteria leucocephala</i>), Glossy Ibises, White Ibises, Teals, Pintails, and Shovellers. The migratory birds include Red-Crested Pochards, Blackwinged Stilts, Avocets, Common Red shanks, Wigeons, Gadwalls and Cormorants, Garganys, Herons, Flamingos among others. See the pictures of birds at Lake Kolleru. Kolleru lake contains numerous fertile islets called lankas, and many of the small ones get submerged during floods. The origin of unusual depression which forms the bed of the lake is unknown, but it was possibly the result of an earthquake. Therefore, many ancient villages get submerged in the bed of the lake as a result of floods and earthquake.

Indian Lakes, Table 1 (Continued)

Changes over the last years	Kolleru lake is suffering from the unsatisfied greed of people and selfish interests of mankind who is exploiting the lake's integrity. Thousands of fish tanks were dug up effecting converting the lake into a mere drain. This had a lot of impact in terms of pollution leading to even difficulty in getting drinking water for the local people. This is besides the loss of ecological diversity and intrusion of seawater into the land masses and its fallout in terms of adverse influence of rainfall pattern in this region. This imbalance has an adverse effect on the thousands of acres of crop in the upper reaches of sanctuary in view of stoppages of water flow into the sea because of obstruction by bunds of the fish tanks that appeared illegally. Satellite images taken on February 9, 2001 by the Indian remote sensing satellite found that approximately 42% of the 245 km² lake was occupied by aquaculture, while agriculture had encroached another 8.5%. The area under aquaculture consisted of 1050 fish ponds within the lake and 38 dried-up fish ponds, which together covered an area of 103 km². The agricultural encroachments were mostly rice paddies. Surprisingly no clear water could be found in the satellite image. The rest of the lake is being diminished by water diversions or was infested with weeds like elephant grass and water hyacinth.
Biodiversity	The lake was an important habitat for an estimated 20 million resident and migratory birds, including the Grey or Spot-billed Pelican (<i>Pelecanus philippensis</i>). The lake was notified as a wildlife sanctuary in November 1999 under India's Wildlife Protection Act of 1972, and was designated a wetland of international importance in November 2002 under the international Ramsar Convention. The wildlife sanctuary covers an area of 308 km². Rich in flora and fauna, it attracts migratory birds from northern Asia and Eastern Europe between the months of October and March. During this season, the lake is visited by an estimated 20,00,000 birds. The resident birds include Grey pelicans, Asian Open-billed Storks (<i>Anastomus oscitans</i>), Painted Storks (<i>Mycteria leucocephala</i>), Glossy Ibises, White Ibises, Teals, Pintails, and Shovellers. The migratory birds include Red-Crested Pochards, Blackwinged Stilts, Avocets, Common Red shanks, Wigeons, Gadwalls and Cormorants, Garganys, Herons, Flamingos among others.
Recreation	The sanctuary in the lake has the following watch towers for sighting the birds. Atapaka: 1.5 km from Kaikaluru to see varieties of waterfowl. Murthiraju tank 8 km from Nidamaru East Chodavaram: 53 km from Eluru where Open Bill Storks nest in colonies from July to December. The sanctuary is approachable from all four sides of the lake by road, directly to the following places: Atapaka – 2.5 km from Kaikaluru town, Bhujabalapatnam – 6 km from Kaikaluru town, Murthiraju Tanks – 8 km from Nidamaru, Gudivakalanka – 3 km from Gudivakalanka or 15 km from Eluru. Nearest city is Vijayawada, which is 65 km by road or rail. Nearest town is Eluru.
General	Kolleru lake contains numerous fertile islets called lankas, and many of the small ones get submerged during floods. The origin of unusual depression which forms the bed of the lake is unknown, but it was possibly the result of an earthquake. Therefore, many ancient villages get submerged in the bed of the lake as a result of floods and earthquake. Two copper plates of the early Pallava dynasty have been found in the lake, which trace their history to Langula Narasimha Deva (Langulya Gajapathi Raju) and Ganga Vanshi Orissa king (Oddiya/Oriya raju). According to legend, the Gajapathi fort was located at Kolleti Kota on one of the eastern islands of the lake. The enemy general "muhammadan" (probably a bahamany general) encamped at "Chiguru kota" located on the shores. In some ways, the lake protected the Oriya forces. The enemy finally tries to excavate a channel, the modern-day Upputeru, so that the water of the lake would empty into the sea and the level would fall so that they could attack the Gajapathi Fort. The royal Oriya army general sacrificed his own daughter, named "Perantala Kanama," to propitiate Gods and ensure his success against Muhammadan. Therefore, the channel was called Perantala Kanama. Sri Peddinti Ammavari Temple is one of the oldest and famous temples found in kolleru. The Suryavanshi Gajapatis of Orissa, on the height of their power in the fifteenth century, ruled over a kingdom extending from the Ganges River in the north to the Kaveri in the south under Gajapati Kapilendra Deva. But, by the early sixteenth century, the Gajapatis lost great portions of their southern dominion to Vijayanagar and Golconda. The Gajapatis were a medieval Hindu Suryavamsi dynasty of Kalinga-Utkal Orissa who ruled large parts of Andhra Pradesh, West Bengal, Bihar, and Madhya Pradesh. During the glorious reign of Kapilendra deva, the first Suryavamsi Gajapati emperor, the boundary of the Kalinga empire (Ancient Orissa) stretched from River Ganges in North to Kaveri in South and from Amarkantak in West to Bay of Bengal (Kalinga Sagara) in East.
Lake	Osman Sagar lake, Hyderabad, AP
Location	Osman Sagar, popularly known as Gandipet, is in the Indian city of Hyderabad.
Location on map	17°23'N 78°18'E/17.383°N 78.3°E

Indian Lakes, Table 1 (Continued)

Surface area	The lake is around 46 km ² , and the reservoir is around 29 km ² .
Inflow	Musi River
Outflow	Musi River
Type of lakes	Osman Sagar, popularly known as Gandipet, is an artificial lake
Changes over the last years	This lake had served drinking water for Hyderabad city but due to increase in population it is not sufficient for water supply to Hyderabad city and so now it is used for public recreation.
Recreation	A princely guest house called Sagar Mahal, overlooking the lake, now a heritage building, was built as a summer resort of the last Nizam. It is located on the banks and has the best view of the lake. Andhra Pradesh Tourism Department currently runs the place as a resort. The breeze of the lake is very pleasant and has been popular with the locals since The Nizam's time. It is a popular tourist destination, especially after the rainy season when the reservoir is full, and its parks, resorts, and amusement park are a major attraction.
General	Osman Sagar was created by damming the Musi River in 1920, for providing drinking water source for Hyderabad, and also saving the city from floods, on the lines of which Hyderabad suffered in 1908. It was during the reign of the Last Nizam of Hyderabad, Osman Ali Khan, and hence the name.
Lake	Himayat Sagar, Hyderabad, AP
Location	Himayat is located about 20 km from Hyderabad in Andhra Pradesh, India. It lies parallel to another artificial lake Osman Sagar and it is smaller in size among both.
Location on map	17°18'N 78°21'E TO 17.3°N 78.35°E
Surface area	The storage capacity of the reservoir is about 3.0 TMC.
Inflow	Musi River
Type of lakes	An artificial lake.
Changes over the last years	The Himayat Sagar and Osman Sagar reservoirs provided continuous water supply to the twin cities of Hyderabad and Secunderabad until recently but due to growth in population it was not sufficient for water supply to Hyderabad city. The Engineer at the time of construction is Late Khaja Mohinuddin s/o Mohammed Hussein, Madri.
Commercial use	The grassy area adjoining the lake is an ideal picnic and recreation spot. The road atop the bund is popular for a good road drive.
General	The construction of reservoir on Esi, a tributary of Musi River, was completed in 1927, for providing drinking water source for Hyderabad, and also saving the city from floods, which Hyderabad suffered in 1908. It was built during the reign of the Last Nizam of Hyderabad, Nizam VII, and so it is named after his youngest son Himayat Ali Khan.
Lake	Saroornagar lake, Hyderabad, AP
Location	Saroornagar lake is a lake in Hyderabad, India.
Location on map	17°21'21"N 78°31'38"E TO 17.35584°N 78.52714°E
Surface area	40 ha. The maximum depth is 6 m.
Type of lakes	An artificial lake
Changes over the last years	From the year of its creation in 1626, the lake remained largely clean until 1956 when Hyderabad expanded. It is one of the five major water bodies in Hyderabad. After 1956 when Hyderabad became the state capital of the Andhra Pradesh, the city witnessed unprecedented population growth, industrialization, and agriculture using synthetic fertilizers and insecticides. Inevitably, untreated domestic sewage, solid waste, and industrial effluents entered into the catchment area of this lake. Spread over 40 ha, the lake was restored by the Hyderabad Urban Development Authority in 2003–2004 at a cost of US\$4.44 million. As a part of development, two sewage treatment plants with the capacity to treat 250 million liters of sewage a day were installed. In addition to this, tourism-centric facilities such as a boating facility in the lake, a children's park, and a restaurant have come up. Four years after the installation of the sewage treatment plant, the officials reported 95% of sewage being treated. With the groundwater conditions improved, migratory birds returned to the lake in big numbers. In 2007, 2.0 ha of park area was developed alongside the lake at a cost of US\$333,000. The park featured sculptures, ornamental landscape, boating facility, and an environment education center.
Biodiversity	The lake was restored by the Hyderabad Urban Development Authority in 2003–2004 at a cost of 20 crore (US\$4.44 million). After the restoration of the lake, migratory birds returned to the lake in big numbers a few years later.
Governing authority	After the restoration, the civic agencies have taken necessary steps that the lake does not get polluted because of the annual immersion of Ganesh idols. In addition, steps have taken to curb unauthorized construction near the lake bed. However by 2009, the filtration unit of the sewage treatment plant stopped functioning properly. As a result of this, the lake was getting polluted with domestic waste.

Indian Lakes, Table 1 (Continued)

Lake	Pulicat lake in Andhra Pradesh and Tamil Nadu
Location	45 km north of Chennai.
Climate	Temperate humid climate
Surface area	The lake area is about 72,000 ha (including swamps of 20,000 ha) out of which 46,000 ha is in Andhra Pradesh and 26,000 ha is in Tamil Nadu. The lake is about 60-km long and 5–15 km wide. Average depth of the lake is about 2 m.
Inflow	Fed by two rivers separated from Bay of Bengal by Sri Hari Kota Island. The lake is separated from the sea by a shoal or sediment bar. During monsoon season due to high flood in Pelar river the shoal gets overflowed and lake and sea become one body.
Type of lakes	A natural lake
Ecological status	Pulicat lake has also been given status of bird sanctuary.
Changes over the last years	The marine silt in the islands contains thin layers of gypsum deposited from the seawater during recent time. Sedimentation from catchment area in Andhra Pradesh as well as Tamil Nadu is reducing the lake's capacity.
Commercial use	The lake is used for drinking, fishing, navigation, etc.
Governing authority	Andhra Pradesh Government and Tamil Nadu Government
Lake	Ooty lake, Tamil Nadu
Location	The lake is located in Ooty district in the state of Tamil Nadu, India.
Location on map	11°24'22"N 76°41'18"E to 11.4061°N 76.6882°
Altitude	2,240 m above mean sea level.
Surface area	3.885 km ² , maximum length is 2.5 km, and maximum width is 140 m.
Inflow	The lake was formed by damming the mountain streams flowing down Ooty valley.
Outflow	
Type of lakes	An artificial lake.
Changes over the last years	The lake was initially used for fishing. The lake which breached thrice, completely emptying itself, originally extended up to the present day market. Ferries were used to get across the lake. The lake gradually shrunk in size giving place to the present race course, the bus stand, and the lake park.
Recreation	The Boat house established alongside the lake, which offers boating facilities to tourists, is a major tourist attraction in Ooty.
Governing authority	The Tamil Nadu Tourism Development Corporation on behalf of the Tourism Department took the possession of the lake in the year 1973, for implementation of boating facilities.
General	It was constructed in 1824 by John Sullivan, the first collector of Ooty.
Lake	Veeranam lake, Tamil Nadu
Location	Veeranam lake is located 14 km SSW of Chidambaram in Cuddalore district in the state of Tamil Nadu in South India, 1 km from Sethiyathope.
Location on map	11°20'10"N 79°32'40"E to 11.33611°N 79.54444°E
Surface area	It has a catchment area of 25 km ² .
Inflow	This Veeranam lake gets water from kollidam via Vadavar River.
Type of lakes	It is a reservoir, intermittently filled during monsoon season
Commercial use	The lake located 235 km from Chennai, India, is one of the water reservoirs from where water is planned to be supplied to Chennai.
Studies undertaken	The opening chapter of the much celebrated book <i>Ponniyin Selvan</i> is set on the banks of the Veera Narayanar lake. Kalki gives an elaborate description of the features of the lake and the way multiple rivers flow into the lake. He also makes a reference to the fact, that Ramanujacharya decided on the number of peetas based on the number of openings in the lake.
General	Veeranam lake was created during Chola period in the tenth century, built from A.D. 1011 to 1037 and is a 16 km (10 mile) long dam in northern Tamil Nadu. Ironically, the lake remains dry for a major part of the year.
Lake	Kodaikanal lake, Tamil Nadu
Location	Kodaikanal lake, also known as Kodai lake is located in the Kodaikanal city in Dindigul district in Tamil Nadu, India. A railway line extended from Chennai to Tirunelveli with an intermediate station at Ammaianayakkanur (later renamed Kodai Road) was built in 1875, to provide a gateway to Kodaikanal town and there on to the lake through a foot trek of 18 km from the railhead. The nearest railheads to the lake presently are the Kodai Road Railway Station at 80 km and the Palani Railway Station at 64 km distance, from the town. Madurai (at 121 km) and Coimbatore (at 135 km) airports are the closest to the Lake. Kodai lake is well connected by road with regular bus services operating to Madurai, Palani, Kodaikanal Road, Theni, Dindigul, Thiruchirappalli, Kumili, Erode, Bangalore, and Coimbatore.

Indian Lakes, Table 1 (Continued)

Location on map	10°14'N 77°28'E 10.23°N 77.47°E
Climate	The lake catchment experiences an average annual rainfall of 1,650 mm. The climate is salubrious with summer temperatures of 19.8°C (max) and 11.3°C (min) and winter temperatures of 17.3°C (max) and 8.3°C (min).
Altitude	2,133 m above mean sea level.
Surface area	24 ha with average depth of 3 m and maximum depth of 9 m.
Inflow	An earthen dam was constructed to create the lake in a marshy stretch where three streams flowed.
Outflow	The outflow from the lake forms the waterfall of 180 ft, called the Silver Cascade, 8 km downstream of the lake outlet.
Type of lakes	A freshwater man-made lake. The lake is star-shaped, centrally located in the town of Kodaikanal, and is surrounded by lush green hills of the northwestern Palani hills range, which is the main watershed for the lake.
Ecological status	<i>Flora</i> <i>Strobilanthes kunthiana</i> or Kurinji flower which blooms once in 12 years in the lake's surrounding Palani hills ranges Kurinji (<i>Strobilanthes kunthiana</i>), a unique flowering plant is reported from the catchment area of the lake. It is reported that this flower last bloomed in 2004 and that it blooms once in 12 years. Hill-plantain fruits and plums are popular in the area. <i>Aqua fauna</i> The lake has moderate to dense growth of macrophytes of all types. The littoral zone of the lake is reported to be rich in periphytic biota associated with macrophytes. Diatoms, protozoans, and rotifers which are also associated with macrophytes are found in the lake. Many aquatic insect larvae and adults, molluscs, cladocerans and the fish <i>Danio aequipinnatus</i>, <i>Rasbora daniconius</i> and <i>Gambusia affinis</i> are reported. Rainbow trout and common carp are the main fish found in the lake. The fish yield as per past records was 5.3 kg/ha/year.
Changes over the last years	Human health risk assessment of the physicochemical parameters of the lake water reveals the following: 1. As per microbial analysis, the water is not potable and needs to be processed prior to domestic use. 2. Several ecological factors have influenced the plankton diversity and abundance. 3. Eight aquatic macroinvertebrate taxa have been identified. 4. Tourists and nearby residents are causative factors for lake contamination and water pollution. 5. Encroachment of the banks of the lake by buildings has violated the court order which prohibits constructions within 200 ft from the banks of the lake. 6. The impact on the quality of water is transitory as compared to closed water body. 7. High pollution loads of organic matter from hotels and other commercial establishments around the lake are causing pollution. 8. Study conducted by the Department of Atomic Energy confirmed that Kodaikanal lake has been contaminated by mercury emissions.
Recreation	Over the years a boat club, boathouse, and boat service (with Rowing boats and Pedaling boats and a public ferry) for the public and tourists have become fully functional and is of aesthetic significance for tourism. Boat Pageant and Flower Shows are a regular feature in the summer season which attracts tourists.
Studies undertaken	The Ministry of Environment & Forests, Government of India has initiated a Centrally Sponsored Scheme called the National Lake Conservation Plan (NLCP), since June, 2001, on 70:30 cost sharing basis between the Central Government and the respective State Government, with the objective of restoring and conserving the polluted and degraded lakes in urban and semi urban areas in the country. On the basis of studies carried out, 62 lakes including the Kodaikanal lake in Tamil Nadu have been identified as polluted and degraded requiring conservation. Treatment and eco-restoration works for the Kodaikanal lake were undertaken by the Government of Tamil Nadu with funds provided by the Government of India, under the above stated cost sharing formula, by the National Lake Conservation Plan (NLCP) of the Ministry of Environment and Forests, to abate pollution and, thereby benefit the local and floating population. The project envisaged Bio remediation, Sewage Treatment, Low cost sanitation Facilities, awareness, de- Weeding, Interception and Diversion Works, Fencing, Horse sheds, Data Collection and Dredging, at a total cost of about Rs 10.33 crores (US\$2.6 million).
General	Sir Vere Hentry Levinge, the then Collector of Madurai, was instrumental in creating the lake in 1863, amidst the Kodaikanal town which was developed by the British and early missionaries from USA. The lake is said to be Kodaikanal's most popular geographic landmark and tourist attraction.

Statistics of Indian lakes and studies undertaken on Indian lakes

The statistics of lake water resources in India are scarce. Research conducted after 1947 addressed the ecological, environmental, socioeconomic, and limnological aspects of lakes. Comprehensive statistics of number of lakes have not yet been assessed. A national inventory of lakes entitled "The All-India Wetland Survey" established by the Government of India initiated a study during the 1960s and could only be able to give a broad assessment of wetlands in the country by 1984.

Depending upon the depth of water and uses, the lakes are known by different names in different parts of the country like Jheels, Bheels, Marshes, Talab, and Tank.

Summary of geography, hydrology, ecology, and research undertaken for some of the important lakes in India is given as a table (see Table 1). The positions of the lakes are shown on the map of India (see Figure 1).

Organizations involved in study of lakes of India

Various organizations that are in leading role to study the ecological and limnological aspects of lakes are the following:

Governmental organizations

1. Ministry of Environment and Forests
2. Planning Commission
3. Ministry of Water Resources

Indian Lakes, Figure 1 Map of Indian lakes.

4. Ministry of Agriculture
5. Indian Board for Wildlife
6. Forest Research Institute
7. Ganga Water Authority
8. Institute of Wetland Management and Ecological Design
9. Environmental Monitoring Organizations
10. National Eco-Development Board
11. National Institute of Oceanography in Goa

Nongovernmental organizations

1. Bombay, Natural History Society
2. WWF – India
3. UNDP/UNESCO
4. French Institute, (Pondicherry)
5. Ecological Society, (Pune)
6. Wildlife Preservation Society of India (Dheradun)
7. Tourism and Wildlife Society of India (Jaipur)
8. Assam Valley Wildlife Society (Guwahati)

Academic institutions

1. Andhra University, Visakapatnam
2. Annamalai University, Annamalai (Tamil Nadu)
3. Barkatullah University, Bhopal
4. D.N.R. College, Bhimavaran
5. Guwahati University, Assam
6. Jawaharlal Nehru University, New Delhi
7. University of Jodhpur, Jodhpur
8. University of Kashmir, Srinagar
9. Osmania University, Hyderabad
10. University of Rajasthan, Udaipur
11. Indian Institute of Technology, Roorkee
12. Sourashtra University, Rajkot, Gujarat
13. Pondicherry University, Pondicherry

National Institute of Hydrology is the only institute engaged in hydrological studies of lakes through its headquarters at Roorkee and also through its Regional Centers at Jammu, Patna, Guwahati, Belgaum, Kakinada, and Sagar.

INITIAL MIXING OF POLLUTANTS

Magnus Larson
 Department of Water Resources Engineering,
 Lund University, Lund, Sweden

Synonyms

Near-field mixing of pollutants

Definition

The initial mixing of pollutants in a lake or a reservoir refers to the processes which mix discharged polluted water with receiving (ambient) water in a zone near the discharge point, where the initial properties of the discharge are important for the mixing processes. Initial properties of the discharge include fluxes of volume, momentum, and buoyancy, as well as geometric characteristics of the discharge. Beyond the zone of initial mixing (i.e. far field), only the properties of the ambient (e.g., *hydrodynamics*, *stratification*, and geometry) will determine the mixing.

Lakes and reservoirs are often used as receiving waters for different types of pollution discharge, for example treated waste water, industrial process water, and cooling water from power plants (Jirka et al., 1996). The discharge of the polluted water typically occurs through a nozzle, or a system of nozzles, as a buoyant jet with a certain initial volume (Q_o), kinematic momentum (M_o), and kinematic buoyancy (B_o) flux. Dimensional analysis is often employed to characterize the buoyant jet and its mixing with the ambient. In such analysis, based on Q_o , M_o , and B_o , two length scales emerge (Fischer et al., 1979), namely $l_Q = Q_o/M_o^{1/2}$ and $l_M = M_o^{3/4}/B_o^{1/2}$. The length scale l_Q quantifies the distance over which Q_o constitutes a significant portion of the local jet volume flux (i.e., the entrained ambient water and Q_o is of the same order). Thus, for distances from the nozzle (s) much larger than l_Q , Q_o will not be of significance. The length scale l_M represents the distance over which the buoyancy generates a momentum flux similar to M_o . For $s \gg l_M$ the effect of M_o is negligible and the buoyant jet becomes a plume. Thus, the extent of the initial mixing zone is often defined based on l_M , since $s \gg l_M$ implies no influence from the initial conditions. Relationships for different jet quantities in the near field, such as velocity, volume flux, and dilution rate may be developed in terms of l_Q and l_M .

If a jet discharge is affected by a boundary, the length of the initial mixing zone could be determined by the location of this boundary. The lake water surface and bottom represent such boundaries (for positively and negatively buoyant jets, respectively), but *stratification* may also act as a boundary.

The highest pollutant concentrations are found in the zone of initial mixing, and the impact on *water quality* is expected to be the largest in this zone. However, since the mixing to a large degree is a function of the initial conditions, it is feasible to reduce the impact through a proper design of the discharge arrangements. In general, the dilution rate is considerably larger in the near field compared to the far field.

INTERNAL SEICHES

Ulrich Lemmin
 ENAC, Ecole Polytechnique Fédérale Lausanne (EPFL),
 Lausanne, Switzerland

Definition

An internal seiche is a standing wave produced in the interior of a lake at the thermocline level.

When wind blows over a lake, a storm surge is produced that causes the thermocline to tilt in the opposite direction (Figure 1). Once the wind ceases, the thermocline, which forms a sharp interface due to the strong density gradient, begins to oscillate around the nodal point in the center of the lake. This is the point that experiences no vertical motion during a seiche cycle (Figure 1). Maximum amplitudes are observed at the antinodes at the ends of the lake basin. This phenomenon was first interpreted as an internal seiche by Watson (1904).

To determine internal seiche periods, the effect of stratification must be considered. It is assumed that an observed stratification profile can be approximated by a two-layer profile in which the density of each layer is constant. The Merian equation valid for “surface seiche” periods must be modified so as to take into account the difference between the water density of the epilimnion (ρ_1) above and the hypolimnion (ρ_2) below the thermocline. Furthermore, the mean thickness of the epilimnion, h_1 , and the hypolimnion, h_2 (Figure 1), enters into the calculation. The restoring force for this oscillation is proportional to the product of gravity and the density difference between the two layers (the relative buoyancy).

The following equation for internal seiche periods can be obtained:

$$P_n = \frac{2L_b}{n} \sqrt{\frac{(h_1 + h_2)}{h_1 h_2 g}} \quad (1)$$

This is the modified Merian equation for internal seiches with n being the wave mode. Here, $g = g(\rho_2 - \rho_1)/\rho_2$ is the reduced gravity. Although this equation was derived for rectangular basins, it was also found to give good estimates for real lakes. Uninodal internal seiches of the mode $n = 1$ have been found to be a widespread, dominant resonant response of stratified lakes to wind stress. Periods of internal seiches are much longer than those of “surface seiches” and are typically in the range of hours (about 76 h for $n = 1$ in “Lake Geneva”).

Using the two-layer assumption, the ratios of the surface inclinations η_1/η_2 and the horizontal velocities v_1/v_2 in the epilimnion and the hypolimnion, respectively, can be approximated by

$$\eta_1/\eta_2 \approx -g'h_2/gh \text{ and } v_2/v_1 \approx -h_1/h_2. \quad (2)$$

Due to the small density difference between the epilimnion and the hypolimnion, seiche amplitudes, η_2 ,

Internal seiches, Figure 1 Definition sketch for a two-layer approximation of a uninodal internal seiche in a stratified rectangular lake basin. *Black dot*: nodal point, *A*: antinodes, *dashed line*: still water reference level of the thermocline, *arrows*: mean orientation of water mass movement.

are typically several meters high (2). Consequently, the currents in the two layers are of the order of several cm s^{-1} , with epilimnion currents being stronger than those in the hypolimnion (2). These currents are comparable to other water movements in lakes. Horizontal currents in internal seiches are strong near the surface and bottom and minimal at mid-depth. The rate of decay is determined by boundary friction and is higher for shallow basins or basins with irregular shape. A numerical procedure to determine internal wave periods and current estimates in irregular shaped basins has been proposed by Lemmin and Mortimer (1986).

Internal seiches are found in lakes throughout the stratified season and can be regular and persistent for long time periods (Figure 2a). Their period is well approximated by the modified Merian equation (1). The effect of

changes in the density difference between the two layers and to some extent also in layer thickness over the stratified season is reflected in the strong seasonal variation of the internal wave period (Figure 2b). Higher mode internal seiches, most often with smaller amplitudes than the first mode, have been observed in lakes. In Lake Baldegg, seiches up to $n = 5$ were simultaneously detected.

The two-layer approximation for the temperature profile is a strong simplification, since the temperature in lakes varies continuously with depth. If a three-layer approximation is made, second vertical mode internal seiche periods can be estimated which are longer than the first mode periods. In Lake Baldegg, the fundamental second vertical mode period was 28.9 h compared to 9 h for the first vertical mode. Second vertical mode seiches result in a periodic change of thermocline thickness.

Internal seiches, Figure 2 Internal seiches in Lake Baldegg (Switzerland; from Lemmin, 1987). (a) Temperature recordings at 15-min intervals at 12.5-m depth at stations 180 and 182 at opposite ends of the lake basin in November 1978. Triangles indicate the period calculated by the modified Merian formula. (b) Seasonal variation of the period of the first mode internal seiche oscillation in 1980.

In large lakes, the influence of Coriolis force transforms a standing internal seiche into a Kelvin wave with the standing seiche pattern shown in [Figure 1](#) rotating counterclockwise (in the northern hemisphere) around the lake basin. It has the same period as a standing internal seiche.

JAPANESE LAKES

Takashi Asaeda¹, Ryuichiro Shinohara²

¹Institute for Environmental Science and Technology,
Saitama University, Saitama, Japan

²National Institute for Environmental Studies,
Tsukuba-City, Ibaraki, Japan

Synonyms

Inland water bodies of Japan; Reservoirs of Japan

Definition

Lake. A lake is an inland and permanent body of water containing a considerable amount of fresh or saline water.

Reservoir. A reservoir is an artificial lake.

Eutrophication. A heavy load of nutrients in a body of water.

Algal bloom. A great increase of phytoplankton in a body of water as a result of eutrophication.

Natural lakes and their formation

Many Japanese lakes are geologically isolated natural waters, not connected to an ocean or river. Some of them were formed by intrusion of seawater into the offshore land after the last glacial age. Shallow inner bays were formed; sediments transported by river inflows were then accumulated in the bays and isolated the water from the sea. Therefore, many lagoons, such as Lake Kasumigaura, Lake Saroma, Lake Shinji, and Lake Ogawara, are located along the coastal line. Among the five lakes around Mt. Fuji (Lake Motosu, Lake Shojin, Lake Sai, Lake Kawaguchi, and Lake Yamanaka), Lakes Onuma, Chuzenji, and Inbanuma are, in fact, rivers that were dammed with accumulated debris from the surrounding volcanoes. The accumulation of decaying plant materials also interrupted river flows and created inundated areas.

Lakes created by this mechanism - Lake Ozenuma, for instance - are relatively small.

Since Japan is situated in a volcanic zone, many lakes have been created due to its geological features. Diastrophism is a mechanism by which many lakes, such as Lakes Biwa, Suwa, and Kizaki, were formed. The development of these lakes is associated with seismic faults. Lakes formed in volcanic craters or calderas are called crater lakes. Lakes Tazawa, Ashino, Towada, Inawashio, Akan, and Kuttara belong to this group and are generally deep with relatively small catchment areas. Lakes Mikazukinuma and Nougaike in Kiso and Lake Barato on Hokkaido were created due to severe river erosion. [Figure 1](#) shows the major Japanese lakes and their origins.

Reservoirs

Since 8 CE, more than 200,000 irrigation ponds have been constructed in Japan. Seventy percent of these ponds were constructed in western Japan, as in the Kinki district (near Osaka) and around the Seto Inland Sea, due to the scant annual precipitation of this area. The largest pond, Mannoike, with an area of 1.4 km², was constructed in 9 CE. These irrigation ponds are of two major types: dammed rivers and swamps surrounded by embankments. The latter group is usually flat and shallow and has a special ecosystem. From ancient times, various types of management practices, such as drying up (Maezono and Miyashita, 2004) or harvesting of overgrown plants, have been conducted by local people to maintain these bodies of water. Therefore, the ponds provide suitable habitats to various kinds of aquatic flora and fauna. They have high biodiversity and can harbor many endangered species (Kunii, 1991; Jiang and Kadono, 2001).

Since the 1950s, many dams have been constructed on mountainous rivers to control floods; the reservoirs formed, thereby, have been used to generate hydroelectric

Japanese Lakes, Figure 1 Locations of major Japanese lakes. F and S represent lakes with fresh and saline water, respectively. Each lake's origin is shown by the numbers: 1 – fault lake; 2 – caldera lake; 3 – volcanic lake; 4 – dammed lake; 5 – lagoon; and 6 – other.

power and to supply water for various utilities. Since the reservoirs were created along the valleys, they are long, narrow, and deep, and thus, they have relatively small storage capacity and short retention period of water regardless of the height of the dam. In total, there are approximately 3,000 dams, of which 14% are used for hydroelectric power generation, 36% for irrigation, 19% for flood control, and 12% for more than one purpose. The largest reservoir in Japan is the Tokuyama reservoir, with a storage capacity of 660 million cubic meter, although the height of the dam is 161 m.

History of Japanese natural lakes

There were many shallow lagoons in the flat plain and coastal zone before 17 CE, when many of them were reclaimed and converted to rice fields. Since the Meiji

era 150 years ago, due to increasing urban population, the surrounding area of lakes has become densely inhabited. As a result, lakeshores have been further reclaimed to develop residential areas. Since 1945, land gained from reclamation area has totaled approximately 347 km² (Ministry of Environment, 1996), which corresponds to ~13% of the total lake area.

Dynamics of lakes and oxygen condition

Since they are located in a temperate zone, most of the freshwater lakes in Japan are holomictic (Akitomo et al., 2009a, b). Their hypolimnion is oxygenated at least once a year, inhibiting the formation of an extreme anoxic zone at the bottom; therefore, they are relatively rich in oxygen. For example, in Lake Biwa, the average dissolved oxygen concentration of the lower layer was 7.1 mgL⁻¹

between 1991 and 2009 at the Imadzu Oki Chuo station (LBERI, 2011). Brackish water lakes, on the other hand, have strong saline stratification, which inhibits convective mixing except for shallow lakes, and the lower layers of polluted lakes, such as Lake Abashiri (Mikami et al., 2002), Lake Obuchi (Ueda et al., 2005), and Lake Shinji, are highly anoxic, which causes mortality even to benthic organisms.

Since the reservoirs are deep and narrow, the wind disturbance therein is weaker. Therefore, once the catchment is developed, the hypolimnion easily becomes anoxic with an increasing inflow of pollution. In western Japan or near large cities with relatively dense population and dairy farming on the gradual mountain slopes, inflows are often highly eutrophic. Hypolimnetic anoxic zones have been found to develop in many reservoirs between September and October.

Water quality

Since the 1960s, many Japanese lakes, particularly those in suburbs or large cities, have become polluted due to urbanization and industrialization. Between 1974 and 2001, the worst water quality in terms of chemical oxygen demand (COD) was observed in Lake Teganuma (Shinohara and Isobe, 2010). Cyanobacterial blooms have appeared in many Japanese lakes in recent years due to eutrophication. For example, in Lake Biwa, cyanobacterial blooms have been appearing particularly in summer since 1983. Since then, various restoration techniques have been tried to address the issue. Flushing with river water (e.g., Lake Teganuma (Asaeda et al., 2005) and Lake Barato (Shinohara et al., 2008)), bypassing of treated sewage water (e.g., Lake Suwa) or polluted inflows (e.g., Urayama Dam), and drying the bottom sediment (e.g., Watarase Reservoir (Asaeda and Rashid 2010)) were successfully implemented. Destratification with bubblers is another commonly used technique to reduce cyanobacterial biomass (Imteaz and Asaeda, 2000). Installation of lateral curtains to isolate eutrophic inflows from the epilimnion was also effective in reducing *Microcystis* and dinoflagellates in some reservoirs (Asaeda et al., 1996, 2001).

The littoral zones of many Japanese lakes were covered with aquatic plants until the 1960s (Kasaki, 1964), before which the plants had been used to prepare organic fertilizer for riparian agriculture. However, since the 1970s, these submerged plants have disappeared from almost all large lakes, except for Lake Biwa. Several causes have been associated with the disappearance of these submerged plants (Watanabe et al., 2005). Eutrophication of the lakes and reduction in transparency is one of the important reasons. These lakes were oligotrophic, and their water was transparent until the 1970s when urbanization and industrialization started around these lakes. Since then, pollutants from the urbanized catchments have been inflowing into the lakes, and aquatic plant population decreased to a great extent. In Lake Towada, for instance, the deeper edge of the charophyte zone decreased from 13 m in 1955 to 7.5 m in 2002. In 1960s, grass carp was

introduced in many lakes, such as Matsubara, Kizaki, Nojiri, and Ikeda. Being voracious herbivores, they ate all the submerged grasses. Although the carps cannot propagate, in lake, they keep grazing on macrophytes until their death.

Since organic pollutants from the catchment areas accumulate at the bottom, sediment has been dredged from many lakes to remove the pollutants from lake. Consequently, bottom irregularities were formed that have led to an anoxic zone on the bottom. Due to dredging, seed banks of aquatic macrophytes were removed, and water depth reduced near the shoreline. The exploitation of the shoreline due to embankment construction around the lakes was prominent in many large lakes during flooding. As the embankment was constructed near or even inside the water to gain more land, it separated land and water and exploited the shoreline. The continuity of shoreline vegetation communities was lost. These processes also affected submerged vegetation communities. The reduction in vegetation by this mechanism is evident at Lake Kasumigaura. The disappearance of submerged aquatic macrophytes also coincided with the usage of chemical herbicides in agricultural fields located in catchment areas.

Exotic species

Ecosystems of many Japanese lakes are suffering from introduced exotic species. Exotic predatory fish, especially *Micropterus salmoides* and *Lepomis macrochirus* (Centrarchidae), are prominent in many Japanese lakes. They were introduced into Japan, to be used for human consumption, in 1925 and 1960, respectively. Starting in the 1970s, they were introduced into many lakes to promote sport fishing (Azuma, 1992), which eliminated many Japanese native fishes. This incidence posed a serious threat to the lake's ecosystem and inland fisheries (Takamura, 2007).

Lake Biwa

Lake Biwa is the largest lake in Japan and is a freshwater lake. Its total surface area is 670.3 km², and it is 27.5 km³ in volume. The deepest point is 103.6 m. Lake Biwa is an ancient lake, originated through diastrophism approximately 4–6 Ma ago, and is one of the oldest lakes in the world, following Lake Baikal and Lake Tanganyika. It is a mesotrophic lake with approximately 6.0 m of Secchi depth. Until 1952, Lake Biwa had approximately 40 shallow lagoons along its shoreline, which provided habitats for various species (Mori, 1980). The lake had extremely high biodiversity, with more than 1,000 plant species, including more than 50 native plants, such as *Silurus biwaensis*, *Silurus lithophilis* (Siluridae), *Gnathopogon caeruleus*, *Sarcocheilichthys variegatus microoculus*, *Sarcocheilichthys biwaensis* (Cyprinidae), *Vallisneria asiatica* var. *biwaensis* (Hydrocharitaceae), and *Potamogeton biwaensis* (Potamogetonaceae). Since 1952, the water level has been regulated down for flood protection, and most of the lagoons were reclaimed.

Since then, the landscape of the lake has changed remarkably, and the population of the flora and fauna inhabiting the lake had been diminishing until a recent renovation. Submerged plant coverage has increased substantially since the end of the 1990s, especially at the southern basin, which is approximately 4 m deep (Haga et al., 2006). Approximately 43% of the total basin was covered in 2000. The colonization is supposed to be the regime shift of the water transparency. In 1994, the water level of the lake was drawn down by 1.23 m, which is believed to trigger the germination of submerged species (Hamabata and Kobayashi, 2002).

Lake Kasumigaura

Lake Kasumigaura, a shallow lake, is the second largest in Japan (220.0 km² in total area). Though the lake is separated into several waters now, it originated as part of a large lagoon. Its water was brackish until 1963 when a gate was constructed to preclude the brackish water's intrusion into irrigation and domestic use. Due to the inflows of sewage and refractory dissolved organic matter from the catchment (Imai et al., 2001), the lake was eutrophicated and has been suffering from cyanobacterial blooming. The blooming was caused by *Microcystis aeruginosa* until the 1980s when the dominance shifted to *Oscillatoria*. The switch of the cyanobacterial species is thought to be the increase in N/P ratio in water from ~8 to 16. The shoreline was covered with emergent plants (Sakurai, 1990; Nishihiro et al., 2006) until the construction of the surrounding embankment, which reduced their population to a great extent. Fisheries of Japanese smelt (*Hypomesus nipponensis* (Osmeridae)), icefish (*Salangichthys microdon* (Salangidae)), carp, and Japanese eel have been popular in the lake. The introduction of *Ictalurus punctatus* (Ictaluridae), however, has been causing many problems in recent years.

Effect of climate change

The effects of global warming are evident in some Japanese lakes. In Lake Biwa, although all the layers are mixing, the mixing time has been delayed. The layer mixing usually occurs in January; however, it was delayed until the beginning of March in 2007 (Yoshimizu et al., 2010). In the Sagami and Tsukui reservoirs, 40 km west of Tokyo, the destratification system to protect algal blooming, which had been working very well for a decade, has not worked for the last few years. In addition to the increased warming of the epilimnetic water, the cold water inflow due to snow-melt is being reduced (Asaeda and Rashid 2010). Although more investigation is required, climate change and warming seem to be affecting Japanese lake conditions.

Summary

Japanese lakes and reservoirs are an integral part of inland aquatic ecosystems. They are rich in biodiversity and provide many important functions in land–water interfaces. Due to anthropogenic reasons, especially urbanization and industrialization, the water quality of the lakes and

reservoirs has deteriorated noticeably in last few decades. As a result, a number of aquatic flora and fauna have disappeared, and many of them are on their way to extinction. Though many mitigation approaches have been adopted and the situation has improved to some extent in recent years, the issue has come forward again due to global climate change. Therefore, more research should be allocated to keeping Japanese lakes and reservoirs functional.

K

KATSE DAM: LESOTHA HIGHLANDS WATER PROJECT

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Description

The Katse Dam is located in Lesotho in the Central Maluti Mountains in the Malibamatso River ([Figure 1](#)). The dam is of the concrete arch type with a height of 155 m. The

primary purpose of the dam is to supply water to the Republic of South Africa (RSA) and to generate hydropower (110 MW). The reservoir has a total storage of 1950 hm³ ([Table 1](#)). The dam was commissioned in 1998 as part of the Lesotho – RSA Highlands Water Project ([Figure 2](#)).

The water is delivered by a series of tunnels by way of the Rivers Caledon, Ash, and Wilge and eventually into the Vaal River to RSA.

The Mohale dam (height 153) and the Muela dam were also built under the Lesotho – RSA Highlands Water Agreement and commissioned in 2004.

KINGAIRLOCH HYDROELECTRIC SCHEME

Reginald W. Herschy
Hydrology Consultant, Reading, UK

Introduction

People have been harnessing water to perform work for thousands of years. The Greeks and Chinese used water wheels for grinding wheat into flour and for powering wood and textile water mills 2,000 years ago.

However, the technology of using water to create electricity was first established successfully when in the mid 1770s the French engineer Bernard Forest de Belidor developed the vertical-axis turbine.

Worldwide today the installed capacity of hydroelectric power stations is of the order of 750 GW (where $G = 10^9$) supplying some 3,000 TWh (where $T = 10^{12}$).

Hydroelectric power plants may be as small as 100 KW of power to the world's largest, the Three Gorges Dam in China with a capacity of 22,500 MW.

In some countries (Norway, Switzerland, Canada, Brazil, New Zealand, Venezuela, Paraguay, and Austria), hydroelectric power is the main source of electricity.

Hydroelectric projects can sometimes create problems for the environment such as reducing fish population by preventing access to spawning grounds upstream. And indeed, a few dams have been withdrawn because of this and other environmental problems. Nevertheless, although in many cases most of the hydroelectric sites have already been exploited, installations, especially small schemes under 10 MW, continue to be built in many areas of the world. The major advantage of these small projects is their geographic isolation, the elimination of the cost of fuel, their long economic lives, and their production of the least amount of greenhouse gases of any energy source.

One such project recently completed (2010) is the Kingairloch scheme in the UK (see photograph showing dam under construction for [Figure 1](#)).

Kingairloch

Kingairloch hydro scheme is situated in an isolated area of the Western Highlands in Morven; the scheme is one of

Kingairloch Hydroelectric Scheme, Figure 1 Dam under construction.

renewable investment and comprises a power station with a horizontal Francis turbine, a 6-m-high concrete gravity dam, two main intakes, two high pressure GRP pipelines, and three buried pipe aqueducts.

The development of the scheme concept was based on using the existing reservoir at Loch Uisge and raising it by 3 m. The new reservoir capacity is of the order of 700,000 m³. This gives storage of 1.4% of annual runoff and allows 3 days generation at full load with no inflow. The reservoir gives considerable benefits in greater flexibility, the ability to maintain compensation flows through dry spells and easier control and greater efficiency of the turbine which runs at a fixed load of 3.5 MW.

Power generation is a function of flow and head, and in this case, the head is 143 m and the discharge is 3.23 m³/s.

The dam is 110 m in length made up of 30-m and 50-m abutments, a 20-m overflow spillway and a 10-m inlet structure. Abutments are of mass concrete while the central section is reinforced. The dam also includes fish passes and provision for releasing water if necessary.

KIS-BALATON AND ITS EFFECT ON LAKE BALATON WATER QUALITY

István Tátrai¹, Kálmán Mátyás²

¹Balaton Limnological Research Institute of the Hungarian Academy of Sciences, Tihany, Hungary

²Transdanubian Water Authority, Kis-Balaton Laboratory, Keszthely, Hungary

Description of Lake Balaton

Lake Balaton is the largest calcareous shallow lake in Central Europe and is situated in the western part of Hungary, in Transdanubia (46°62'–47°04'N, 17°15'–18°10' E). The lake is primarily used for recreational purposes (Figure 1). The surface area is 596 km², but the mean depth is only 3.2 m and the mean water residence time is 5 years (Table 1). The only outflow is at the eastern end of the lake where a control gate was built in 1863. River Zala enters the westernmost basin and drains about half of the catchments (5,775 km²). There are 51 minor inflows, 20 of which are permanent.

Kis-Balaton and Its Effect on Lake Balaton Water Quality, Figure 1 Lake Balaton scenery during a calm sunny day. (Photo by Balaton Club Co., <http://www.balatonclub.hu>).

Kis-Balaton and Its Effect on Lake Balaton Water Quality, Table 1 Hydrological, chemical and biological characteristics of Lake Balaton

Water surface	59,000 ha
Length	77 km
Width	8–16 km
Maximum depth	11.2 m
Mean depth	3.2 m
Water residence time	3–8 years
Mean annual water temperature	12.2°C
pH	8.4–8.7
Conductivity	660 µS cm ⁻¹
Maximum summer chlorophyll-a values	
Eastern basin	17.6 µg L ⁻¹
Middle basin	47.1
Western basin	60.6

The water of the lake is frequently turbid because of sediment resuspension and calcite precipitation (Istvánovics et al., 2004).

During the past 30–35 years, Lake Balaton has been heavily impacted by human activities. High-point and non-point sources of nutrient loading have led to heavy eutrophication (Herodek, 1986). Cyanobacterial blooms occurred during summer, and massive repeated fish kills were observed (Bíró, 1997). Eutrophication and habitat perturbation (e.g., decreased water level fluctuations, climate change leading to increased temperature, decreasing drainage area) led to a drastic decrease in the number of fish species, stock recruitment success, and increasing water temperature in Lake Balaton (Specziár et al., 1997; Bíró, 2000). To combat eutrophication, the Hungarian government has initiated several action plans aimed to reduce the external nutrient loading and nutrient retention. To accelerate recovery of Lake Balaton, chemical and biological restoration methods have been applied between 1985 and 2002.

In order to manage nutrient loads and enhance improvement in water quality of Lake Balaton, Kis-Balaton Water

Protection Reservoir (KBWPR) was constructed in the lower Zala River Valley, the main inflow to the lake (Figures 2, 3). In this entry, we describe the actions taken to reduce the external and internal loadings and the response of the ecosystem to the reduction.

Description of the Kis-Balaton water protection reservoir

Construction of the Kis-Balaton Water Protection Reservoir (or System) (KBWPR) ($46^{\circ}78'N$, $17^{\circ}27'E$) (Figure 2) was planned in two phases (Figure 3). The first

Kis-Balaton and Its Effect on Lake Balaton Water Quality, Figure 2 The two phases of Kis-Balaton Water Protection Reservoir: Phase I (left) during early summer and Phase II (right) during fall. (Photo by Transdanubian Water Authority, Kis-Balaton Laboratory at <http://www.kisbalaton.hu/kepek.html>).

Kis-Balaton and Its Effect on Lake Balaton Water Quality, Figure 3 Lake Balaton and its watershed area. The Kis-Balaton Water Protection Reservoir (KBWPR) is enlarged. Experimental area (16 km^2) of Phase II has been operating since 1992. The rest of Phase II is planned to be operating by 2012 (A, input to the KBWPR I; H, output of the KBWPR II; F, input to Lake Balaton).

phase (Phase I), called Hídvégi Pond, started to function in 1985. It is a hypertrophic pond, with a surface area of 18 km², a mean depth of 1.1 m, and a mean water retention time of 30 days. The pond, called “Cassette,” was implemented within the first phase with emergency purposes during flooding and has an average depth of 1.2 m and an area of 350 ha. Phase II, called the Fenéki Pond, was planned to have a total surface area of 57 km², a mean depth of 1.2 m, and water retention time of 90 days. This area should be the recipient of an additional 25–30% nutrient load that originates from the watershed. In November 1992, a 16-km² experimental area of the Fenéki Pond was flooded. Of this area, 90% is covered by macrophytes, primarily reeds. Phase II is planned to be completed by 2012.

History of nutrient load reduction

A series of management measures decreased external nutrient loads of Lake Balaton by about 50% (Table 2) (Istvánovics et al., 2007; Tátrai et al., 2000, 2008). Loads from point sources were reduced by sewage diversion from about two thirds of shoreline settlements in the period 1983–1986 (all along Basin 4 and along the southern shores of Basin 3) and by introducing P precipitation in large sewage treatment plants of the catchments (including the largest city with 60,000 inhabitants; 1991). Management of diffuse loads was credited to the KBWPR in

the lower Zala River (Figure 4). By 1988, Phase I of the KBWPR has developed into a hypertrophic reservoir with a reasonable efficiency of nutrient retention (on average, 27%; Istvánovics and Somlyódy, 1999). A part of the Lower Reservoir (Phase II) was opened in November 2002. In this area, dense reed stands retain mineral nitrogen and particulate forms of nutrients with efficiencies over 90% but release 2–10 t of soluble reactive phosphorus (SRP) each year. In addition to the management measures, incidental events also contributed to the reduction in nutrient loads. Fertilizer application dropped to one tenth of the former level in 1989 when Hungarian agriculture collapsed and no recovery occurred yet.

Kis-Balaton and Its Effect on Lake Balaton Water Quality, Table 2 Loads of total P in the pre- (1980–1988) and post management (1989–2002) periods (After Clement, 2000)

Basins	ton P year ⁻¹		g P m ⁻² year ⁻¹	
	1980–1988	1989–2002	1980–1988	1989–2002

2	78	44	0.54	0.31
3	46	25	0.25	0.13
4	48	26	0.21	0.11
Total	268	138	4	2

Kis-Balaton and Its Effect on Lake Balaton Water Quality, Figure 4 Map of Lake Balaton showing the reconstructed wetland area of the Kis-Balaton Water Protection Reservoir (KBWPR). Numerals indicate the four basins of Lake Balaton.

Kis-Balaton and Its Effect on Lake Balaton Water Quality, Figure 5 Long-term variation in the estimated external and internal loading to Lake Balaton. The average yearly concentrations of (a) soluble reactive phosphorus (SRP) and (b) total phosphorus (TP). (c) Development in chlorophyll a in the western (1) and eastern (4) basins of Lake Balaton between 1980 and 2002 (mean $\pm$ 1 SD). Arrows from left to right indicate function of Phase I and Phase II of the Reservoir system.

Repeated droughts during 1989–1993 and particularly in 2000–2003 decreased surface runoff and diffuse loads to negligible levels. During this period, the maximum summer chlorophyll a values dropped to 18 in Basin 4 and 61 $\mu\text{g L}^{-1}$ in Basin 1 (Table 1). Considering the timing of various management measures, we selected 1988/1989 as a somewhat arbitrary turning point between pre- and post-management periods (Table 2).

Effect of nutrient load reduction on water quality

In-lake mean concentrations of both SRP and TP declined by about 50–60% from the pre-management (1980–1988) to post-management period (1989–2002). Concentration of TP was primarily determined by sediment resuspension. The reduction of the external and internal P loading had altered trophic responses. The most pronounced effects of reduced nutrient loading were found for

phytoplankton. The annual average chlorophyll-a concentration within few years decreased by nearly 20% during the early post-management period. While interannual fluctuations remained substantial, the mean chlorophyll a concentration in Basin 1 decreased steeply following 1995. A similar decrease after some delay could also be observed in the other basins of the lake. We found some indication of reduced fish predation on crustaceans. The yearly mean ratio of cladoceran was higher by 10% in the post-management period as compared with the pre-management one without any changes in species composition of cladoceran. This change occurred in concert with the reduction in the fish stock by fishery and angling (Tátrai et al., 2008) (Figure 5).

A reduction in the external and internal P loadings resulted in improvement of the water quality 10 years following first intervention, even in the hypertrophic western

part of Lake Balaton (Istvánovics and Somlyódy, 2001) Enhanced internal P loading after the reduction in external nutrient load is clearly an important factor explaining the duration of recovery in shallow lakes. As the mobile P content of the sediments today approaches a new steady state and former species assemblages have reappeared to replace Cyanobacteria during summer, we may expect a long-term stability in water quality of Lake Balaton. Lakes with many years of high P loading can develop a P surplus, where the supply of soluble P exceeds demands of phytoplankton and a large portion of TP occurs in the dissolved form. In Lake Balaton, a substantial decline in chlorophyll *a* occurred at decreasing SRP concentrations at yearly mean concentration around $20 \mu\text{g L}^{-1}$ following the first management measure during the post-management period, a decrease in, first and foremost, the internal loading.

LADOGA LAKE AND ONEGO LAKE (LAKES LADOZHSKOYE AND ONEZHSKOYE)

Nikolai Filatov¹, Leonid Rukhovets²

¹Northern Water Problems Institute, Karelian Research Center, Russian Academy of Sciences, Petrozavodsk, Karelia, Russia

²Saint-Petersburg Institute for Economics and Mathematics, Russian Academy of Sciences, St. Petersburg, Russia

Introduction

Lake Ladozhskoye and Lake Onezhskoye (Ladoga and Onego, respectively; Onego on the contrary river Onega in Archangelsk Region) are the greatest lakes in Europe. Ancient names of Lake Ladoga are Nevo, Al'desk, Al'da, Al'dagas, Al'doga, Al'dagen, Aldea, and Veniemmeri. In ancient times, Lake Onego was called Anizskoye from Finnish name *Ääninen järvi*, *ääni* means voice or sound. These European lakes were called the Great because their dimensions are larger than of any other lakes in Europe (Gusakov and Petrova, 1987; Rukhovets and Filatov, 2010). Lakes Ladoga and Onego located between 58°54'–61°47'N and 60°55'–62°55'N, respectively, are of the northernmost lakes among the world Great lakes. These lakes with river system represent the unified lake system. Lake Onego is connected with Lake Ladoga via River Svir, Lake Saimaa via River Vuoksi (Burnaya), and Lake Il'men via River Volkhov (Figure 1). Lake system is linked with Gulf of Finland in the Baltic Sea via River Neva. The surface area of Lake Ladoga is 17,891 km², average depth is 51 m with a maximum of 230 m, and volume 908 km³; it ranks among the top 15 world's freshwater lakes (Chernjaeva, 1966) (Another dimensions published by (Naumenko 2001)). Lake Onego surface area is 9,600 km², average depth is 30 m with a maximum

of 120 m, and volume 292 km³. The watershed of Great European Lakes is 258,500 km² which extends through North-western European Russia (80%), the eastern part of Finland (19.9%), and Byelorussia (0.1%). The watershed includes the large lakes Il'men and Saimaa. Lakes Ladoga and Onego are an important link in the Caspian-Baltic-White Sea waterway system. Ladoga and Onego are also a key section in the drainage basin of the Baltic Sea. The catchment is made up of four secondary watersheds: Ladoga (28,400 km²); Onego-Svir (83,200 km²); Saimaa-Vuoksi (66,700 km²); and Il'men-Volkhov (80,200 km²) watersheds (Rumyantsev and Drabkova, 2002).

The system of Great European Lakes was generated between contrasting crystalline Fennoscandian (Baltic) shield and Russian plates composed with Paleozoic rocks. In the area of crystalline shields, the ancient Earth rocks granites and gneisses are found at the surface with age of up to 2 billion years. The history of Ladoga and Onego Lakes development is linked with the initial stage of the Baltic Sea formation – the Baltic system of near-glacial lakes. After complete release from glacial cover about 4.5 thousand years ago, the northern shores of the lakes underwent the isostatic rise, which continues with low rate up to date. At the end of Pleistocene, pre-Ladoga and pre-Onego were oligotrophic cold water bodies (Davidova and Subetto, 2000). Nearly 4–5 thousand years ago, the formation of modern Baltic Sea practically was completed. The Neva River, 74 km long, became the only outflow from Lake Ladoga to the Baltic Sea with the average discharge equaled to 2,500 m³/s. The final formation of the Neva River and the whole system of Great European Lakes were formed less than 2,000 years ago. By this time, Lake Ladoga level attained the modern magnitudes (about 4–5 m above the sea level).

The peculiarities of the evolution and generation of Ladoga and Onego Lakes' basins and watersheds had

Ladoga Lake and Onego Lake (Lakes Ladozhskoye and Onezhskoye), Figure 1 Lakes Ladoga and Onego and their watersheds.

created such specific features of the coast line as its high embayment in the north and regular smoothness in the southern, southeastern, and southwestern parts. A high degree of similarity is observed in the northern parts of the Lakes coasts – a large amount of narrow long coves, bays, and fjords, elongated from North to South or from North-west to South-east, and existence of skerries. Ladoga and Onego Lakes in general are very similar to Great American Lakes in their origin, coasts types, bottom relief, and the contrast between the northern and the southern parts of the basins. Lake Onego is the upper one in the system of Great European Lakes.

Since 1933 after the construction of Belomorsko-Baltyisk Canal, Lake Onego was connected with the

White Sea and joined the united system, linking the White, the Baltic, and the Caspian seas. In 1953 on the River Svir (length 224 km), an Upper Svir (Verhnesvirskaya) hydropower station was constructed, since then the lake water regime was regulated and the Upper Svir reservoir was formed. Now, two large hydropower plants operate on the Svir River.

The climatic regime within Lake Ladoga and Lake Onego watersheds could be characterized as transitional one from marine climate to continental. The region is referred to the Atlantic-Boreal region of moderate climatic zone. Prevailing air masses of Atlantic and Arctic origin is typical here all through the year. In average, 550–750 mm of precipitation is registered here. The winds of southern,

south-western, and western directions prevail in the region. Mean annual air temperature varies from 0°C in the north to 3°C in the south. The coldest month is January (with average temperatures –12°C, –13°C in the northern part and –9°C, –10°C in the southern part). A year's warmest month is July (14°C, 15°C in the northern part and 16°C, 17°C in the southern part).

Lakes Ladoga and Onego are completely covered with ice during cold winters; in warm winters, the ice covers only part of lakes. Beginning of ice formation takes place in the middle of November. Ice cover thickness on lakes can reach 1 m and even more in some years. On Lake Ladoga during winter period, quasi-steady polynya exists, dividing ice cover of the coastal area (fast ice) and central part of the lake. Lakes Ladoga and Onego ice cover destruction usually takes place in May, but in cold spring, floating ice may be observed in June. Important characteristics of lakes' thermal regime according to many years of observations (Rumyantsev and Drabkova, 2002) correspondingly are spring thermal bar arise in Lake Ladoga on May 1, in Lake Onego on May 10, and autumn thermal bar correspondingly in the middle of October–November.

These lakes belong to the dimictic type of lakes, where the complete mixture of water body takes place twice a year – in spring and in autumn. The large catchment area located in different landscapes determines the wide diversity of natural and anthropogenic factors affecting the lake ecosystem dynamics. The considerable dimensions of the lakes and slow water exchange (the ratio of the lake volume to annual inflow), that is the retention time for Lakes Ladoga and Onego, is 12 and 16 years, correspondingly. These are the reasons of ecosystem conservatives. Complicated morphometry of the lake basin and its large proportions define heterogeneity of hydrophysical, hydrochemical, and hydrobiological processes in different parts of water body. The variability of limnetic parameters, typical for the deep large lakes, is especially intensified under the heavy and essentially always nonuniform anthropogenic impact.

Water balances of the lakes in km³ for Lake Ladoga and Lake Onego correspondingly are: river discharge to lake 72.3 and 16.8 and precipitation–evaporation 3 and 1.8. Annual amplitude of water level fluctuations are 70 cm (Lake Ladoga) and 75 cm (Lake Onego) (Gronskaya, 2008). The aquatories of these Lakes were divided into four limnetic zones (Rumyantsev and Drabkova, 2002; Rukhovets and Filatov, 2010), each of which plays a special role in ecosystem functioning.

The cyclonic type of circulation (currents) of waters dominates at these lakes. In winter in these lakes covered completely or partially by ice, the circulation of water is very weak (less than 2 cm/s), and the maximum current speed in summer is about 70–100 cm/s.

The phosphorus concentration in these lakes limited the lake productivity level, which accelerated the beginning of the next phase of anthropogenic eutrophication.

Lake Ladoga is a mesotrophic with a low alkaline neutral water and slightly alkaline bicarbonate class of Ca group lake. (In the region of Sortavala town it is eutrophic, of

satisfactory state). By the level of development phytoplankton state in 1960, Lake Ladoga was a typical oligotrophic lake with low level of bacterioplankton which was relatively uniformly distributed over the water basin. By late 1970s, the level of phytoplankton and bacterioplankton development increased significantly. Macrophytes–108 species; phytoplankton–380 species including *Bacillariophyta*–154, *Chlorophyta*–126, *Chrysophyta*–14. Zooplankton has more than 380 species. The main groups are rotifers (*Rotatoria*), protista (*Protozoa*), cladocerans (*Cladocera*), and Copepods (*Copepoda*). These species are mostly inhabitants of the pelagic zone. In the coastal zone, the abundance (tens of thousands in 1 m³) of indicators of polluted water was noted – indicators of significant quantities of organic matter (*Brachionus calyciflorus*, *Keratella cochlearis*, *Polyarthra dolichoptera*, *Asplanchna priodonta*, etc.). Macrozoobenthos together with the meiobenthos organisms and about 600 species invertebrates live at the bottom of Lake Ladoga. In profundity of the open part of aquatory, *Oligochaeta* created 55–80% of the biomass of biocenoses at the bottom. Lake Ladoga is inhabited by more than 50 fish species (Rumyantsev and Drabkova, 2002). Only 10 species have the most economical importance: whitefish, smelt, perch, roach, pikeperch, vendace, bream, pike, salmon, and ruff. The Red Book of Russia includes the Siberian sturgeon and Volkhov whitefish. General fish catches in the 1950s ranged from 1,500 to 6,700 t in a year. In average, it made 5,000 t per year. During the past decade, stocks of lake-river fish, as the Volkhov whitefish, salmon, and trout (lake trout) have strongly decreased. And during the years 2003–2009, the annual catch was 622 t per year. The state of the Ladoga seal population is good enough; the total number of seals is estimated at about 5,000 individuals.

Lake Onego is oligo-mesotrophic with water which has the same characteristic as the water of Lake Ladoga. Water in Lake Onega has better quality than water in Lake Ladoga.

Bacteriocenoses on the lake aquatory are characterized by high variability of its features. Macrophytes are presented by 75 in the lake. Phytoplankton of Lake Onega includes 780 species. These species are: *Bacillariophyta*–390, *Chlorophyta*–203, *Chrysophyta*–78, and *Cyanophyta*–63. Zooplankton of Lake Onego has similar features to the zooplankton in Lake Ladoga. It contains 254 species: *Rotatoria*–123, *Cyclopoida*–29, and *Cladocera*–82. Lake Onego contains more than 500 species and forms of macrozoobenthos, which are mostly concentrated in the coastal zone. Outside coastal zone, it is mainly represented by four groups: *Oligochaeta*, *Amphipoda*, *Bivalvia*, and *Chironomidae*. Ichthyofauna in Lake Onego is similar in general to that of Lake Ladoga. Though salmon inhabits Lake Ladoga, its fishery is significant in Lake Onego only. In Lake Onega, 16 species of fishes are considered as marketable fish, such as salmon, lake trout, palia, vendace, whitefish of various ecological forms, grayling, smelt, perch, burbot, pike, roach, perch, ruff, bream, ide, and ablet. Endangered species include sturgeon, sabrefish, and catfish. Vulnerable species include lake

salmon, trout, grayling, and the category of rare and so far safe species – various ecological forms of whitefish.

Until the mid 1960s, industrial activities on the watershed influenced very little on the state of the ecosystem and the water quality in Lake Ladoga. The Lake preserved its status of an oligotrophic water body, as it had at the beginning of the twentieth century. Insignificant bacterial pollution was registered only in the vicinity of the waste water outlets of the paper mill enterprises. The anthropogenic load of phosphorus (P) on Lake Ladoga, the origin of the lake eutrophication, has increased since the early 1960s. Until the mid-1980s, the average phosphorus concentration, P_{tot} , reached 28 $\mu\text{g P/l}$, changing the lake status from oligotrophic to mesotrophic (Rumyantsev and Drabkova, 2002). The economical collapse in Russia in the 1990s led to a certain decrease of the phosphorus load on Lake Ladoga (from 6,100 t P/year in 1984–1995 to 4,000 t P/year in 1996–2003). The anthropogenic load on Lake Onego in 1970–1986 resulted in the evolution of the lake trophic status from oligotrophic to mesotrophic only in semi-closed bays. In the last 15 years, the lake as a whole has retained its oligotrophic status. Currently, P_{tot} in the lake is 8–10 $\mu\text{g P/l}$. Lake Onego is now at the stage of ecosystem destabilization and in the initial phase of eutrophication. The phosphorus load on Lake Onego changed from 1,003 t P/year in 1992–1997 to 786 t P/year in 2001–2002.

Several numerical experiments were performed by means of mathematical model for the determination of admissible phosphorus load which preserves the ecosystem stability. This load turned out to be 4,000 t P/year (Rukhovets and Filatov, 2010). These experiments reveal that Lake Ladoga would preserve its weakly mesotrophic status. In a case where the initial higher load would be decreased to 4,000 t P/year, the lake returns to a weakly mesotrophic status in 5 years. For Lake Onego, simulations of the lake ecosystem functioning under a different type of phosphorus load showed that the load of 800 t P/year and 15,000 t N/year is the most desirable for the lake ecosystem stability.

Economic development in the region of the Great Lakes of Europe is at a very high level. There operate numerous extracting and processing industries, most of them water- and resource-intensive, such as pulp-and-paper mills, oil refineries, chemical plants, wood processing, non-ferrous metal processing and food industry enterprises, hydropower and heat power plants, building material industries, etc. The region possesses mineral, forest, and balneological resources. During Soviet times, agriculture was quite well developed. It is now gradually recovering, but application of fertilizers – sources of nutrient pollution – has dropped several times. Lake Ladoga catchment area has a population of 3.5 million people, including 2.7 million urban residents. Population density in the Russian part of the catchment is 12.4 person/km². Agricultural areas cover 11% of the area. Several hydropower plants operate on a number of rivers in the catchment (Rumyantsev and Drabkova, 2002). In 2006, water withdrawal from the lake catchment amounted to ca. 1,500,000 m³, of which about 750,000 m³ were

utilized by St. Petersburg communal facilities (Rukhovets and Filatov, 2010). Intensive economic development results in substantial human impact on water objects, which is made up of effluents from industries, communal facilities (point sources), fish farming, and agriculture, as well as dissolved and suspended impurities from arable land, pastures, and fertilized and abandoned land (non-point sources or diffuse loading), which are the main causes of pollution and eutrophication of the water bodies. The greatest hazard for the lake ecosystems among point sources is direct wastewater discharges. The important changes have taken place in the past few decades in the issue of water protection from wastewater impact.

LAKE ICE

Esko Kuusisto
 Finnish Environment Institute, Fresh Water Centre,
 Helsinki, Finland

Introduction

Millions of inland water bodies freeze over each winter. In February, the total extent of lake ice cover in the Northern Hemisphere probably exceeded 2 million square kilometers,

in over 50 countries. On both hemispheres, there are also lakes which are perennially frozen; the summer thickness of ice is in excess of 5 m in some Antarctic lakes. The extreme case is Lake Vida, which has 19 m of ice overlying a brine with a salinity seven times that of seawater (Doran et al., 2003). High mountain lakes may have permanent ice cover even in the equatorial zone.

In North America, seasonal lake ice cover can develop as far south as 33°N, in Eurasia 26°N. Among the 15 largest lakes on the Earth, only four are not affected by ice (Prowse et al., 2007). In high mountains, freezing lakes occur in a wide range of latitudes.

Unlike river ice, lake ice is virtually unaffected by man's actions in watercourses and river basins. Only exceptionally do, e.g., thermal effluents, a road embankment, or heavy regulation alter lake ice conditions. Thus nature's fingerprint in lake ice is very pure – a fact which offers many possibilities in climate change research.

Trends in lake ice variables

Many factors have an influence on lake ice formation, growth, and decay. They can roughly be divided into climatic, hydrological, morphometric, and chemical. Of these, the morphometric ones are most stable, having typically very slow rates of changes. The most important chemical factor is the salinity of water, which also rarely undergoes rapid fluctuations.

As to the hydrological factors, a strong throughflow can completely inhibit the formation of ice cover. The factor playing a most important role – and affecting all lakes – is, however, a climatic one: the air temperature. Statistically, it has, e.g., been found to explain up to 60–80% of the variance in the breakup dates of lakes (Livingstone, 1997; Williams et al., 2004; Korhonen, 2005). Therefore the timing of ice-on and ice-off has been modeled in numerous studies on the basis of air temperature alone, and the reverse; historical variations in lake ice phenology have been used extensively as a proxy for ambient air temperatures.

In the widely cited study of Magnuson et al. (2000), the freezing was found to have delayed on the average by 5.7 days per 100 years in a sample of large lakes in the Northern Hemisphere, whereas the breakup had shifted 6.3 days toward an earlier date. Comparable results have been obtained in numerous other studies from North America, Europe, and Asia (e.g., Latifovic and Pouliot, 2007; Franssen and Scherrer, 2008; Punsalma et al., 2004).

In Figure 1, the freezing and breakup dates of Lake Kallavesi in Finland are shown in data series, which cover 177 and 189 years, respectively. Linear trends indicate significant changes toward later freezing and earlier breakup; the duration of ice cover has shortened by almost 1 month. The change seems to have accelerated in the last one and a half decades, although this signal is not very clear yet.

The effect of teleconnections on ice phenology has been demonstrated in several studies. Both Southern Oscillation (ENSO/SOI), Pacific Decadal Oscillation (PDO), and North Atlantic Oscillation (NAO) have left a signal to many

North American lakes (e.g., Ghanbari et al., 2009), the NAO to the lakes of Europe and northern Asia (e.g., Yoo and D'Odorico, 2002).

There is evidence that the sensitivity of freezing and breakup dates is highest near the southern limit of lake ice formation. For example, Weyhenmeyer et al. (2005) found the breakup date to shift around 14 days earlier per 1°C rise in air temperature in southern Sweden, but only 4 days per 1°C rise in northern Sweden. The durations of the ice cover are 0–125 days and 200–250 days, respectively. In many lakes near the southern limit of ice regime the frequency of ice-free winters has already increased. For example, in the 186-year record of Lake Champlain in Vermont, almost half of the 31 winters when the lake has not frozen over have occurred since 1970 (Wake, 2005). Similar development has been reported from Lake Windermere in the English Lake District (George, 2007), from the lakes in the Netherlands (Mooij et al., 2005) and on the Swiss plateau (Franssen and Scherrer, 2008).

The thickness of lake ice correlates much more poorly with air temperature than the freezing and breakup dates. The maximum thickness is not a measure of the severity of winter, but rather a complicated function of snowfall and air temperature patterns. Even with exactly similar negative degree-days and snowfall totals, the maximum ice thickness may vary considerably. However, in some studies numerical estimates have been calculated; e.g., according to Williams et al. (2004) the maximum ice thickness would be reduced by 7 cm per 1°C rise in mean annual air temperature.

Several long time series of lake ice thickness are available in Finland. Some series from observation sites in southern and central Finland have indications of a thinning trend, some in the northern Finland of a thickening trend until 2002 (Korhonen, 2005). In recent years, lake ice has been relatively thin in the north, and, e.g., for Lake Inari the fitting of two regression lines with a turning point at 1972 seems to be more appropriate (Figure 2). However, no firm conclusions can be drawn.

The effects of ice on the lake water balance

The onset of ice cover greatly reduces the energy fluxes between the lake and the overlying air. One consequence is a sharp decline in lake evaporation. If a lake stays free of ice cover, evaporation may continue at a high rate and even increase.

In spring the surface water of a lake starts to warm after the breakup date, with a consequent increase of evaporation. For example, in Lake Pyhäjärvi in southwestern Finland the evaporation in May in 1936–1973 was estimated to range from 8 to 81 mm, largely depending on the breakup date (Kuusisto, 1975).

As long as the control section at the lake outlet remains ice-free, floating ice cover does not have any influence on the outflow from the lake. Particularly in small and shallow lakes, the control section will be partly or completely ice-covered, with a consequent reduction in outflow.

Lake Ice, Figure 1 Time series of the freezing and breakup of Lake Kallavesi in eastern Finland. According to the linear trends (significant at the level of 99.9%), the freezing date has shifted 15 days later in 1833–2009, while the breakup date has shifted 12 days earlier in 1822–2010.

In the Finnish network of 250 discharge stations, 95 are located at lake outlets without artificial structures. In a severe winter, around 60 of these lake outlets have ice cover, in a mild winter only 40. In those, the outflow is typically 20–50% of that in the ice-free conditions.

As a consequence of rising air temperatures, the ice cover at lake outlets will become thinner or even disappear. At the same time, inflows into the lakes will increase. Together these factors may lead to a considerable enhancement of winter outflows from the lakes.

In the vicinity of large lakes, the ice cover – or better the lack of it – has a well-known influence on snow storms. When cold air passes for long distances over relatively warm waters of a large lake, moisture and heat are picked up and huge amounts of snow may fall on downwind shore. In the Great Lakes region, heavy lake-effect snowfalls occur along the southern and eastern shores of particularly Lakes Superior, Erie, and Ontario (Delcourt et al., 2002). For example, in the winter season of 1976–1977, the total snowfall in Hooker, New York, was 1186 cm with a period of over 50 consecutive days with snowfall (Heidorn, 1998).

Climate change may increase the severity and frequency of lake-effect snowstorms, because open water conditions in winter months will probably become more prevailing in many northern lakes. The phenomenon may also be created over some lakes, where it is unknown at the present climate. These may include the largest lakes in the Finnish Lake District.

Some ice is immobilized on the shallow areas of the lake during winter. This effect can be particularly pronounced in reservoirs with a high drawdown, leading to a loss of release capacity and the amount of electricity produced. At the Gouin Reservoir in Quebec, the immobilized portion represents up to 8% of water available for hydroelectricity production (Seidou et al., 2006).

In the flat northern tundra, there are numerous shallow lakes, which are solidly frozen to the bottom in late winter. For example, on the North Slope in Alaska, even lakes 2 m deep become solid ice (Kovacs, 1978). Most of these lakes have resulted from the thawing of ice-rich permafrost or the melting of snow and ice, as the frozen ground underneath has prevented the water from draining away. The lakes tend to enlarge because of wave action and

Lake Ice, Figure 2 Time series of maximum ice thickness at Lake Kuivajärvi (60°47' N, 23°50' E) and Lake Inari (68°52' N, 28°16' E). All regression lines shown are significant at least at the level of 95%, but interannual variations are large enough to make all conclusions uncertain. Interestingly, the thickest ice in the whole observation series of Lake Kuivajärvi was observed in the winter of 2002–2003; the same was true at almost all measuring sites in southern Finland.

continued thermal erosion of the banks. Climate warming may enhance these processes and also create considerable greenhouse gas emissions.

Snow on lake ice

Snow falling on the surface of a frozen lake forms part of the water storage. A heavy snow load may substantially increase the outflow from the lake in winter months. In a sample of 45 unregulated Finnish lakes, a water equivalent of 50 mm of the lake snow cover increased the outflow on the average by 19% in February (Kuusisto, 1994).

Despite the smoothness of the ice surface, the areal variability of the lake snow cover is often high. This variation is mainly due to the uneven formation of snow ice and the transport of snow by wind. Snow ice tends to form more extensively near shores and congelation ice more extensively in central parts of lakes (Bengtsson, 1986).

Snow cover effectively blocks the penetration of solar radiation into the water mass. Petrov et al. (2005) studied in northwestern Russia a lake with 20–40 cm snow cover. They found the radiation flux at the lower boundary of ice

to be only around 0.2 W m^{-2} in the presence of snow, while the flux increased to $2\text{--}20 \text{ W m}^{-2}$ in mid-April and up to $50\text{--}120 \text{ W m}^{-2}$ in late April.

Lake ice as a nuisance and as a benefit

Lake ice has a multitude of effects both for nature and human activities. The functioning of the lake ecosystem is essentially linked to the freezing and melting cycle. Stratification and mixing of the water mass, exposure to solar radiation, and all energy and gas exchange with the atmosphere depend critically on the presence of ice cover.

Until recently, the winter conditions of ice-covered lakes were considered rather static. This was mainly due to the low research activity; now the interest in various processes in under-ice environment has grown rapidly. It has turned out that variations in weather conditions, particularly those preceding the time of freezing and breakup, may have important impacts for hydrodynamics and consequently to microorganisms and further to higher trophic levels (Salonen et al., 2009).

The thermal expansion of ice is a powerful geomorphic agent on the lakeshores in cold regions. It also causes often

damages to manmade structures. The cracking of ice at the onset of cold spells is a common feature, too, leading to risks for ice traffic. It has even been found to induce harmful vibrations and noise in buildings near the shoreline (Makkonen et al., 2010).

The shortening of the ice cover season as a consequence of rising air temperatures can lead to profound changes in, e.g., biological productivity and diversity. These changes may vary from detrimental to beneficial. The whole lake ecosystem may collapse. On the other hand, wintertime fish kills, which are frequent in many shallow ice-covered lakes, may be eliminated.

For human activities, lake ice is both a nuisance and a benefit. It may hinder transportation by boats and ships, but an opening of an ice road may become possible with the growth of ice thickness. It ends some fishing activities, but creates possibilities for new ones. Wintertime recreation on ice is a common habit in all circumpolar countries. Unfortunately, it can also lead to fatal accidents. For example, in winter 2007–2008, when lake ice in southern Finland was thinner than in any other winter during the last 100 years, over 30 people drowned. It was even discussed that legislative measures might be needed in the future – in some central European countries it is already forbidden to go to lake ice.

Particularly in the eighteenth and nineteenth centuries, the lake ice was also used extensively for cooling purposes. Still in the childhood of the author in the 1950s, most farmers in his village in central Finland had a storage of lake ice covered with sawdust. Some pieces of ice were dug out every day to cool milk containers in a water-filled tank.

The future of lake ice

The sensitivity of lake ice to changing climate has been studied extensively in recent years. Most of these studies are based on empirical relationships between meteorological and ice regime variables. Non-climatic parameters like latitude or lake area have also been used. In general, these relationships have a high statistical significance, if at least several decades of historical data are available.

Can these relationships be used to predict the future of lake ice? In many studies this has been made. However, there is no guarantee that such empirical relationships will be valid in the future, because, e.g., systematic changes in the structure of the energy balance over lakes are possible. Furthermore, increased snowfall may enhance the growth of white ice, which could cause a delay in breakup. Physical lake ice models, involving the use of several meteorological variables, could give more relevant results.

Ground observations related to lake ice have dramatically declined in several countries. This can be partly compensated by remote sensing methods, but there is a risk that many excellent proxy indicators of climate change will be lost.

LAKE MONSTER

Reginald W. Herschy
 Hydrology Consultant, Reading, UK

Introduction

There are many monsters reported to be living in many lakes worldwide. Probably, the most famous is the legendary Loch Ness Monster, renowned for over 1,400 years and with over 1,000 sightings during the last 100 years. In recent times, “sightings” have been mainly between the 1930s and the present without any conclusive evidence of a living animal. Loch Ness is some 23 miles (37 km) long, with an average width of about 1 mile (2 km). The average depth of the loch is 470 ft (145 m), with a maximum depth of 754 ft (227 m) more than the mean depth of the North Sea and a volume of 263,000 million ft³ (7,452 million m³). A survey of the loch was undertaken in 1903 by Sir John Murray during his Bathymetric Survey of the Scottish Lochs, 1897–1909. The loch has a catchment area of 770 sq. miles (2,000 sq. km), and the area of the loch is 22 sq. miles (56 sq. km) (see [Figure 1](#) and [2](#)).

Classification of lakes

Lakes may be classified as *eutrophic* (nutrient rich) and *oligotrophic* (nutrient poor), as is Loch Ness. In any lake, the water stratifies in summer. When this occurs, the upper water, the *epilimnion*, warms in the summer and becomes less dense and floats on the colder water below, the *hypolimnion*. The two layers are separated by a zone of sharp temperature change, the *thermocline*. In productive lakes, nutrients in the epilimnion can become depleted by algal growth and cannot be replenished until winter gales mix the two water layers together. Therefore, the algae die back in late summer. At the same time, the decay of organic matter falling through the thermocline robs the hypolimnion of oxygen. In unproductive Loch Ness, very little organic matter falls through the *thermocline* into the *hypolimnion*. There is, therefore, sufficient oxygen for life in even the deepest parts of the loch. The *epilimnion* temperature in Loch Ness rises to about 12°C, but in the depths, the temperature remains at about 5.5°C. However, it is estimated from the many sonar investigations carried out that the fish stock in Loch Ness is of the order of

20 t, perhaps not enough to satisfy a family of predators. The loch supports mainly brown trout, eels from the Sargasso Sea, Arctic char (some living at a depth of some 200 m), and salmon, which come to spawn from their Icelandic feeding grounds. It is estimated that some 20 t of salmon a year pass through the loch, some within a few days, on their way upstream to their spawning rivers.

The formation of Loch Ness

Some 400 million years ago, the folding and crushing of the Caledonian mountains formed a large fault dividing Scotland in half and stretching as far as Newfoundland. The fault is called the Great Glen, which later held Loch Ness. However, before that, the huge Lake Orcadie stretched from the Moray Firth to the Great Glen. Some of the fish at the time evolved into amphibians as the land mass moved in Devonian and Carboniferous times. And it is known that reptiles evolved into dinosaurs. Ten thousand years ago, glaciers retreated up the Great Glen. Ice-dammed lakes broke through in a succession of floods, leaving traces of “parallel roads” on the hillsides. The land, relieved of the ice burden, has since risen to bring the loch to 16 m above sea level. Loch Ness is connected to the sea by the 7-mile-long River Ness along which migratory fish, mainly of the salmon family, have colonized it. Salmon and eels still migrate to and from the sea, and even seals have no difficulty in entering the loch. There is also a man-made canal built by Thomas Telford and opened in 1822, linking the lochs of the Great Glen into a 60 mile (100 km) passage from sea to sea – from the Atlantic to the North Sea.

It seems certain, however, that the phenomenon has had a significant effect on tourism and the economy of the area, especially in the case of Loch Ness where thousands of tourists and others continue to descend on the loch in search of “Nessie” (including the author!).

Legendary monsters

Legends have it that “dragons” and “worms” once infested the European countryside, for example, the huge “Worm” displayed in the main square in Klagenfurt, Austria. Legends relate how most of the great heroes – Sigurd, Beowulf, Siegfried, King Arthur, Tristan, St. George, and St. Michael – all slew dragons. Other well-known “Worms” include the Lambton Worm (County Durham); the Lyminster Dragon in Sussex; the Yeti, better known as the Abominable Snowman in the Himalayas; Bigfoot (Sasquatch) (US); Ogopogo in Canada; Swamp Ape; Skunk Ape; and Momo, the Missouri Monster. Like the Loch Ness Monster, none have actually been scientifically confirmed.

Tim Dinsdale

In the sixties, the film made by Tim Dinsdale renewed interest in the Monster. Dinsdale, an aeronautical engineer, was one of the most dedicated Monster seekers and spent 27 years in its search until his death in 1987. He published several books on the Loch Ness Monster.

Lake Monster, Figure 1 Map of Loch Ness.

"Sightings" of note of the monster since 1933

In 1933, on July 22, Mr. Spicer, while driving along the road between Dores and Inverfarigaig, was surprised to see a "large animal" crossing the road in front of him and suddenly disappearing into the loch about 30 m away.

Also in 1933, a Mr. Hugh Gray reported "a large animal in the loch about 12 meters away" near Foyers.

Again in 1933, on December 12, Malcolm Irvine and colleagues filmed "the monster" on the loch near Inverfarigaig. In November, Lt. Commander Rupert Gould conducted an analysis of the sightings so far. He described 42 sightings from the period May 1923 to May 1933. Gould suggested an airship might be useful to search and investigate the monster, but the suggestion was never taken up.

On January 5, 1934, near Abriachan, a Mr. Grant, a motor cyclist returning home from Inverness, almost collided with a "large animal" about to slip into the loch.

On June 5, 1934, the famous surgeon's photograph showed what appeared to be a large elephant-like animal (the surgeon was actually Dr. Robert Kenneth Wilson, a London gynecologist). The photograph was only exposed as a hoax at the Loch Ness Centre 60 years later.

One of the best descriptions came from a maid early in the morning of June 5, 1934, in Fort Augustus as she looked out of a window where she worked. She reported "a giant animal with a long neck, small head and elephant skin with two short forelegs." She was about 200 m from the loch and watched the animal for at least 20 min.

Lake Monster, Figure 2 Loch Ness from Drumnadrochit (January 2009).

In 1935, a Dr. McRae claimed to have filmed the Monster with his cine camera for some 5 min. It had “a long neck, a pointed head, small horns and three humps and was about 9 m long.” As a matter of interest, this film is said to be safely in a London bank vault.

During the 1939–1945 war, Loch Ness was under the control of the Navy, and little or no sightings were recorded. Any sightings during the war may be found in the UK Archives in Kew, London. Nevertheless, in May 1943, one of the officers, C.B. Farrel, of the Royal Observer Corps reported a “sighting” of what he took to be the Monster.

In 1952, John Cobb was killed on the loch when his jet-powered boat *Crusader* disintegrated in attempting the world water speed record. The tragic accident was believed to have been caused by sudden unexplained ripples, “an area of disturbed water.” The waves were probably caused by one of Cobb’s own boats.

More recent “sightings” in summary (with numbers in parenthesis) have been the following: 1965 (12), 1967 (25), 1971 (11), 1973 (12), 1975 (9), 1977 (17), 1979 (27), and 1983 (23).

Source for above is Ulrich Magin, as published in Bauer, H., 1986 “The Enigma of Loch Ness” University of Illinois Press.

The following records are less reliable: 1992 (1), 1993 (1), 1996 (9), 1997 (11), 1998 (1), 2000 (1), 2001 (1), 2003 (1), 2004 (1), 2005 (4), and 2007 (2).

The Loch Ness Investigation Bureau (LNIB), during surveys, captured on film 4 “sightings” during 1962 and 1963.

Expeditions and investigations

1933: The Daily Mail sponsored investigation.

Sir Edward Mountain Expedition (1934) placed 20 observers around the loch every day for 5 weeks. Eleven sightings were made, including five photographs, but did not provide conclusive evidence.

Loch Ness Phenomena Investigation Bureau (LNPIB 1962–1972) – observations by members, including Sir Peter Scott, Mrs. Constance Whyte, and David James MP.

Oxford and Cambridge Universities team using 28 kHz echo sounders moved together along the length of the loch.

The LNPIB Sonar Study (1967–1968) volunteers and scientists observed large fast-moving animal objects.

Carroll’s Sonar Study (1969) mobile sonar scan made contact with a strong animate echo for 3 min.

Submersible Investigations (1969) *Pisces* sub from Vickers noted large moving object about 15 m above the bed of the loch.

The Big Expedition (1970) hydrophones deployed at intervals throughout the loch noted strange sounds.

In the summer of 1982, The Loch Ness Project spent 1,500 h of scanning sonar patrol. Forty contacts of unusual strength and depth were recorded.

Loch Ness Project: “Operation Deepscan” in 1987 set up a sonar curtain along the loch using a flotilla of 24 motor launches equipped with Lowrance echo sounders (See [Figure 4](#)). Most of the contacts made were from debris. However, three seemed to move. These could have been seals which are known to visit

Lake Monster, Figure 3 Side scan sonar survey vessel on Loch Ness with, from left, Dr. Robert Rines, Mr. Martin Klein, and Mr. Tim Dinsdale.

the loch each year or possibly some form of unrecognized interference between the sonars.

Loch Ness Project 1981, Sonar Survey of Arctic char found living at a depth of 214 m

Robert Rines' Underwater Studies (1972, 1975, 2001) underwater photos using time-lapse cameras appeared to show animals resembling plesiosaurs (see [Figure 3](#)).
Discovery Loch Ness (1993) researched the ecology of the loch.

Global Water Search Team (GUST) Expedition (2001) sonar contact showed movement on the screen.

Monster Hunt Weekend 1990 Media event providing a focus for foreign television crews, including the British ITV children's program *Motormouth* with a four-man Japanese crew, seemed to show a large animate object moving at speed at the bottom of the loch.

By the end of the 1990s, investigations from 20 universities were under way in collaboration with The Loch Ness Project, including the Rosetta Project (1994) concerned with sediment cores. Project Urquhart (1993) was concerned with the biological condition of the loch.

Lakes with "sightings" of monsters

There are some 265 lakes worldwide where monsters have been reported (of which, surprisingly, 24 are to be found in Scotland alone)!

Following is a selection:

Lake Baikal (Siberia)
Bala Lake (Wales)
Bear Lake (Idaho–Utah, USA)

Lake Brosno (Russia)
Lake Champlain (USA/Canada)
Charleston Lake (Canada)
Faymouth Ency (Cornwall, England)
Flathead Lake (Montana, USA)
Fulk's Lake (USA)
Lough Keane (Ireland)
Lake Kenas (China)
Kleifarvatn (Iceland)
Lago Las Rocas (Chile)
Lago Nahuel Huapi (Argentina)
Lake Manitoba (Canada)
Lake Menbu (China)
Lake Mjosa (Norway)
Loch Morar (Scotland)
Lough Muck (Ireland)
Lago Nahuel Huapi (Argentina)
Loch Ness (Scotland)
Okanagan Lake (Canada)
Lough Ree (Ireland)
Seljordsvatnet (Norway)
Lake Simcoe (Toronto, Canada)
Storsjon (Sweden)
Lake Tahoe (USA)
Lake Tianchi (China)
Lake Van (Turkey)
Lake Varota (Russia)

Search pioneers

The legendary search for giant or unusual animals, either aquatic, amphibious, or other species, has interested many

scientists and others over many years, and the search still goes on. Included in this group of pioneers are:

Herodotus (484–425 BC)
 Lucretius (99–55 BC)
 Pliny the Elder (23–79 AD)
 St. Columba (521–597 AD)
 Olaus Magnus (1490–1558)
 Conrad, Gessner (1516–1565)
 Erik Pontoppidan (1698–1764)
 Anton Oudemans (1858–1943)
 Charles Fort (1874–1932)
 Ivan Sanderson (1911–1973)
 Tom Slick (1916–1962)
 Rene Dahinden (1930–2001)
 Bernard Heuvelmans (1916–2001)
 Ted Holiday (1920–1979)
 Tim Dinsdale (1924–1987)
 Grover Kantz (1931–2002)
 Jordi Magraner (1967–2002)
 Adrian Shine investigator since 1973

Location of sightings and assessment

In considering the location of the “sightings” in Loch Ness, the following places seem to have been the most rewarding (see [Figure 1](#)): Urquhart Castle, Urquhart Bay at Drumnadrochit, Foyers, Dores, Achnahane, Invermoriston, Inverfarigaig, and Fort Augustus.

Hoaxes, perceptions, and illusions

Forty years of surveillance has understandably identified possible illusions or misleading perceptions by sincere eyewitnesses, for example, trees, boats, mirages, logs, deer, wind slicks, and seiches. There have also been hoaxes. One such hoax, related to that mentioned above, is the famous “surgeon’s photograph,” the hoax finally proved by the Loch Ness Centre. Others may have been the result of wishful thinking. However, by far, most of the 1,000 documented sightings of the monster have been made by honest observers who did not seek publicity.

Hypothetical candidates

Adrian Shine of the Loch Ness Project, in his book “Loch Ness,” discusses what animal could survive undetected in a loch too cold for reptiles to reproduce. Some have suggested large eels which did not return to the sea to spawn and instead grew to a huge size. Shine also considers the huge predatory European catfish, the wels. The loch is too cold for them to reproduce, but a single specimen introduced by man could live for a 100 years and so be present for the entire period of the modern sightings record. He also considers the Atlantic sturgeon, one of which was caught in the River Towey in Wales in 1933 and another off the canal entrance in 1871. Indeed, in 1932, a Miss MacDonald saw a crocodile-like creature swimming up the River Ness. Could this have been one of the legendary kelpies (Gaelic, *Each Uisge*) or Water Horses of folklore or even an actual sturgeon? A small

Siberian sturgeon was used in an experiment in a pond at the Loch Ness Centre to be viewed by unsuspecting visitors. Some thought it was a shark, and others, a crocodile, which is reminiscent of the sighting mentioned above. However, the list of suggested real animal candidates is a long one:

1. Giant eel
2. Giant squid
3. Giant pinniped (Oudemans)
4. Long-necked seal
5. Long-necked newt
6. Plesiosaur (Dinsdale)
7. Great sea serpent (Gould)
8. Hypothetical form of vastly enlarged long-necked newt (Gould)
9. Hypothetical type of long-necked seal
10. Animal whose identity remains to be established
11. Animal belonging to a known species (e.g., sea lion) not recognized by observer
12. Animal belonging to a species thought to be extinct
13. Marine creature trapped and evolved from a plesiosaur
14. Sturgeon (Adrian Shine)

How did the animal(s) get into the loch

There are two possibilities. They either have been trapped in the loch for thousands of years or have entered recently perhaps within the last 100 years or so.

Some speculate that at the end of the ice age 10,000 years ago, the ice melted and the sea was raised and flooded the land along inland valleys, and Loch Ness was linked to the sea. The animals swam into the loch but found their return route closed because the land rose, and Loch Ness became an enclosed lake eventually, losing its salinity and becoming freshwater. The other possibility is the River Ness flowing into the sea at Inverness, but the river is probably too shallow to permit the passage of very large animals. The fact that the loch is now some 16 m above sea level rules out the possibility of a tunnel. It should also be noted that the Caledonian Canal has locks at both ends and throughout its length.

The question is still what are they: reptile, amphibian, mollusk, fish, or something that does not fit into any of these types.

The most widely thought is that it is a plesiosaur – a marine fish-eating reptile contemporary with the dinosaurs and thought to have been extinct for 70 million years. This theory was put forward by Dr. Denys Tucker, former British Museum expert. If correct, it would be the greatest zoological find for centuries, and indeed, *Elasmosaurus* of the plesiosaur family is known to have existed in the British Isles.

It seems incredible that the research to date has been carried out on a shoestring budget, though interest has been shown by the British Natural History Museum, Smithsonian Institution, BBC, Freshwater Biological Association, NASA,

Lake Monster, Figure 4 View from Urquhart Castle, Loch Ness showing a flotilla of 24 motor launches equipped with Lawrence echo sounders; some 1,500 h sonar patrols were made, patrolling the loch over a period of a week.

Eastman Kodak, MIT, Academy of Applied Science, and many others, including many universities in Europe and the United States.

Over a thousand people have contributed to the Loch Ness work in one way or another. Many are volunteers to the Loch Ness Investigation and the Loch Ness Project. A list of those completing university dissertations for university degrees may be found on www.lochnessproject.com.

I hope it's there. But I hope they don't find it-because if they do, they'll do something nasty to it.

Dr. David Bellamy, 1991

I am not yet certain of the ending, but in the course of a decade I have watched the plot develop, and an almost empty stage slowly fill with characters – each with a part to play, a contribution to make, however small – to the whole tremendous story.

Tim Dinsdale, 1976

If monsters exist, then science, a mainstay of our conventional wisdom, has ignored the most exciting wildlife mystery in the British Isles; if there are none, then over one thousand people including doctors, clergymen, M.P.s, civic dignitaries and a saint may have lied; unthinkable. Alternatively, they were sincerely and unshakably mistaken; even more worrying!

Adrian Shine, 2006, The Loch Ness Project

It looks as if the existence of a population of very large animals in Loch Ness is about to be finally confirmed.

Sir Peter Scott, 1975 (Review)

Introduction

Glacial lake outbursts have always fascinated scientists but also concerned populations living near glaciers, just as they worry populations living downstream of dams built by humans. Such outbursts have frequently caused catastrophes resulting in the complete destruction of villages and the deaths of hundreds of people. In terms of geomorphology, over the past several decades, quaternary scientists have sought to document the effects of recent and past glacial outbursts to reconstruct the deglaciation history of areas where they prevailed and to show how powerful the outbursts are.

The first goal of this paper is to point out the recent implementation of monitoring networks for glacial dams and glaciers in several parts of the world, with regard to the risk of glacial outbursts.

The second is to bring together and describe the typical features of glaciofluvial landforms partly or entirely created by glacial outbursts resulting from the sudden drainage of glacial lakes and to identify their settings. These features are defined on the basis of the specific characteristics of fluvial corridors, that is, erosional and depositional forms, the characteristics of sediments and their stratigraphic position. This document provides the most up-to-date list of the typical geomorphological features of surfaces reshaped by glacial outbursts (Robitaille and Dubois, 1995; Robitaille, 1989). Throughout the world, in the view of Hugget (1994), Robitaille and Dubois (1995), Robitaille (1989), and several others, various unexplained landforms on the earth's surface are probably the result of catastrophic floods. In fact, as stated by Tricart and Cailleux (1962), generally speaking, it is possible that the role of glacial outbursts has too often been overlooked in the study of glaciofluvial environments. Glacial outbursts, because of their magnitude, first result in spectacular erosion upstream and then displace huge quantities of material that are deposited downstream. Areas of erosion and sedimentation follow

each other, mainly depending on slope variations; major modifications of the streambed and its immediate environment therefore ensue.

Despite the high number of glacial dam breaches that have occurred throughout the centuries, there are relatively few studies concerning the geomorphological consequences of glacial outbursts at inland margins (Table 1) and from alpine and northern glaciers (Table 2).

Monitoring glacial lakes

The occurrence of glacial outbursts and, chiefly, their impact on infrastructure and human lives have been preoccupying populations for centuries. In the Little Ice Age, numerous readvances of alpine glaciers led to breaches in morainic dams, triggering sometimes deadly outbursts. Today, in the context of global warming and with the assistance of increasingly sophisticated tools, the governments of many countries have set up monitoring networks (United Nations, 2002). Accordingly, the behavior of hundreds of glacial lakes has been monitored, sometimes for several decades, for example, in Alaska or in the Canadian or American Rockies (Devaris, 2006; US Geological Survey, 2002), in the Himalayas (Government of Nepal, 2006; United Nations, 2002) or in Iceland (Hardardottir et al., 2005). Monitoring networks, sometimes manned by volunteers, have even been created in the Himalayas and in Iceland, for instance (World Volunteer Web, 2006; UNEP, 2000).

Terminology of lake outbursts

In the literature, several terms have been used to identify the entire phenomenon or its consequences. English speakers use the terms *glacier burst*, *glacier outburst*, *glacial outburst*, *glacier flood*, and *debris flow*. The materials accumulated when glacial lakes are drained are known as *glacier outburst deposits* or *accumulations en nappe de débâcle glaciaire* in French (Robitaille and Dubois, 1995) and differ from *outwash deposits* and *ice-contact deposits*. Since Rabot's work (1905), the term *débâcle glaciaire* has been used by French Europeans to identify the sudden and violent discharge of water from a glacial lake (proglacial and sub-, en-, and supraglacial pockets of water). It therefore means a catastrophic glaciofluvial flood. For French speakers, the term *debacle* is usually associated with a drift ice phenomenon, that is, with flooding in rivers and streams resulting from spring runoff (Georges, 1970), but Baulig (1970), Michel and Fairbridge (1980), and Étongué Mayer et al. (2002) clearly distinguish it from *débâcle glaciaire* or *glacial outburst*.

Glacial outbursts are also known by other names. For example, in Iceland and other countries, the term *jökulhlaup* denotes the violent discharge of sub-, en- and supraglacial pockets of water resulting from subglacial volcanic eruptions (Thorarinsson, 1956; Gomez et al., 2000; Magilligan et al. 2002). In Peru, because they transport huge amounts of sediments, they are known as *alluvione* or *huayco* (Tufnell, 1984).

However, *lake outburst* could be a general term that would include both glacial lake outbursts and those of reservoirs.

Glacial outbursts

There is little reference documents dealing with the geomorphological role of glacial outbursts. However, authors discussing them always highlight their great erosional power and transport capacity. Glacial outbursts are considered events of major, if not catastrophic, importance in fashioning proglacial environments – events that can transport hundreds of thousands of cubic meters of material (Tricart and Cailleux, 1962; Price, 1973; Embleton and King, 1975).

Glacial outbursts are divided into two categories based on their environment: mega outbursts at inlandis margins and outbursts in alpine and northern regions.

Mega glacial outbursts at inlandis margins

The best-known studies of long-ago mega glacial outbursts at the leading edge of inlandis are those concerning large glacial lakes Missoula (Spokane Flood), Bonneville (Bonneville Flood), Regina, and Souris, all located in the center and west of North America, as well as Lake Agassiz, in the east. The large jökulhaups that occur in Iceland can also be included.

In every case, the estimated flows have involved hundreds of thousands of cubic meters per second, and the resulting geomorphological transformations have been varied, significant, and most often erosion related (Dawson, 1992). Most of the landforms are hundreds of square meters or more in size (Figure 1). The deep channels and bars of sediments, for example, have been used as models in interpreting large-scale erosional and fluvial

sedimentation landforms on Mars (Baker and Milton, 1974; Rice, 2006). Table 1 presents the main geomorphological characteristics of the landforms shaped by these mega glacial outbursts. They are mainly deltas, giant current ripples, braided channels incised into the bedrock (basalt), block fields derived from till, large quantities of unsorted sediments, erosion notches, abandoned cataracts, giant kettles, large-scale abandoned dendritic drainage networks, etc. This landscape remodeling may have affected territory over a distance of up to 1,000 km in the case of the outburst of Glacial Lake Missoula in the United States (Ice Age National Scientific Reserve, 2007).

Glacial outbursts in alpine and northern regions

There are many detailed studies specifically pertaining to fluvial corridors remodeled by recent glacial outbursts in alpine and northern regions (Table 2). These glacial outbursts are smaller than those previously mentioned. They involve glacial reservoirs behind dams up to 150 m high (Government of Nepal, 2006), generally containing several million cubic meters of water but sometimes as much as 90–100 million cubic meters (Government of Nepal, 2006), with flow in the order of 500–5,000 m³/s, but that can reach 300,000 m³/s (Hardardottir et al., 2003). Therefore, although the geomorphological transformations may be less varied and less impressive than is the case at inlandis margins, they are nonetheless significant. Moreover, in several cases, the outbursts even occur annually (Hardardottir et al., 2003).

Nevertheless, the power of the water during these glacial outbursts is amazing. In the cases reported, the authors always highlight their great geomorphological effectiveness and their power compared to all other types of glaciofluvial flow (Vivian, 1974). The displacement of

Lake Outbursts, Figure 1 Dry falls. The falls were created following the catastrophic collapse of the ice-dam of “Glacial Lake Missoula.” (Photo: A. Robitaille.)

Lake Outbursts, Figure 2 Breach in till caused by the outburst of an artificial dam (*right* of the photo), lac Beloeil, Québec, Canada. (Photo: A. Robitaille.)

a volume in the order of 4.9 million metric tons has even been reported for a single event (Hardardottir et al., 2005), even reaching 40 million in some cases (US Geological Survey, 2002). A summary of the work on this type of glacial outburst brings to light many geomorphological characteristics related to erosional and depositional processes.

Although there are not many erosion forms, they can be observed in the majority of remodeled fluvial corridors. The main forms noted are deep channels in scarps, erosion terraces carved in till, breached frontal moraines, and landslide scars in scarps. Depositional forms are more varied. Moreover, some of their sedimentary characteristics (e.g., poor sorting, barely discernible structure) are specific to glacial outbursts. The most frequently observed forms are block fields derived from till, outburst deposits, current ripples, coarse-grained alluvial fans, boulder bars, and terraces covered with coarse-grained material, as well as sand spits containing antidunes.

Classification of the typical features of lake outbursts

Analysis of past cases of glacial outbursts, as well as of an outburst at an artificial lake studied in the field (Figure 2) in Québec (Robitaille, 1993; Robitaille and Dubois, 1989), identified seven general characteristics (Table 3). They can be used to reconstruct the events related to glacial outbursts, facilitate the interpretation of specific or complex proglacial environments, and pinpoint where glacial outbursts occurred in formerly glaciated areas. Glacial outbursts may have partly or completely remodeled glaciofluvial landforms and even transformed a glacial environment consisting of till into glaciofluvial landforms.

Dry glaciolacustrine basins

In the case of a proglacial lake, typical forms of dry glaciolacustrine basins are mainly concentrated immediately upstream of the lake's spillway. They consist mainly of wide shallow landslide scars cut into the floor of the lacustrine basin. However, in the absence of both small scarps marking the boundary of the landslide niche and of residual mounds consisting of glaciolacustrine deposits or till, the scars are not very visible in the field. The second characteristic landform is an erosion notch extending into the axis of the spillway, petering out towards the interior of the basin. The notch is generally lined with blocks and bordered by a scarp. Elsewhere in the dry basin, other features contribute to the identification of a glacial outburst: the absence of a strandline below the lower limit of the scouring, the presence of varved glaciolacustrine sediments not overlain by fill material such as sand and gravel. Abandoned dendritic drainage networks mark the sediments of the dry basin's floor.

Breached morainic dams
